## ABSTRACT

Thick gold single crystals of high quality were prepared for Rutherford Backscattering Dechanneling studies by electropolishing and annealing. The variation with temperature of the Random Fraction versus Depth spectrum for $2 \mathrm{MeV} \mathrm{He}^{+}$on $\langle 110\rangle$ gold was extracted from measured Aligned and Random (Energy) Spectra. The measured dechanneling rate showed a sixfold increase in going from $41^{\circ} \mathrm{K}$ to $293^{\circ} \mathrm{K}$ and is in reasonable agreement with calculations made using the Steady Increase in Transverse Energy (SITE) approximation.
I would like to thank my thesis supervisor, Dr. J. A. Moore, for his guidance and exceptional patience throughout this project.
It is also a pleasure to thank Janet Hastie, for typing this thesis with great speed and accuracy; Vicki Migus, for assistance with the diagrams; the technical staff at the McMaster University electron microscope; everyone at the Solid State Physics branch of Chalk River Nuclear Laboratories, for advice and assistance with the dechanneling measurements; J. F. Ziegler and H. H. Andersen, for communicating their recent Stopping Power data; M. L. Swanson and J. A. Davies, for supplying the thick gold single crystals. Special thanks are due to J. Lori at C. R. N. L. for his expert maintenance of the channeling facility throughout our round-the-clock experiments.
Financial support for this project was received from the National Research Council of Canada and is greatly appreciated.

## CHAPTER ONE

INTRODUCTION

## I. 1 THE CHANNELING EFFECT

When a beam of energetic particles (e.g., $\mathrm{MeV} \mathrm{He}^{+}$or $\mathrm{H}^{+}$) is incident on a single crystal target, the depth of penetration of the beam and the yield of physical processes, requiring small impact parameters, are found to be strongly dependent on the relative orientation of the single crystal with the beam direction. This is known as the Channeling Effect. Many instances of this effect were discovered in the early 1960's. For example, when a beam of energetic particles was incident along low-index directions or planes of a single crystal, it was found that the yield of atoms ejected or "sputtered" from the target decreased sharply"; the particles in the beam penetrated the target to anomalously large depths ${ }^{2-6}$ and had lower energy losses on traversing the crystal ${ }^{7}$; the nuclear reaction yield for $(p, \gamma)$ reactions in silicon ${ }^{8}$ and for ( $p, n$ ) reactions in $\mathrm{Cu}^{9}$ dropped sharply. The reduction in yield is considerable. For $2.0 \mathrm{MeV} \mathrm{He}{ }^{+}$ particles incident on the $\langle 110\rangle$ direction in gold, the Rutherford Backscattering yield from the surface of the crystal is $2 \%-3 \%$ of that from an amorphous gold target. The channeling effect requires that the beam direction be within approximately $1^{\circ}$ of the crystal axis or plane direction. A recent review of channeling phenomena, containing an extensive bibliography, has been given by Gemmel1 ${ }^{10}$.

The Channeling Effect has been applied frequently to defect studies in crystals. For example, in an ion-implanted material, it is possible to
measure the location of the impurity atoms within the unit cell and the concentration of displaced atoms caused by the ion implantation damage ${ }^{11-13}$.

## I. 2 THE CONTINUUM POTENTIAL

Lindhard ${ }^{14}$ has given a comprehensive theoretical analysis of the Channeling Effect, in which he describes the axially channeled particle as one which travels almost parallel to the crystal axis, making a series of correlated glancing collisions with a row or "string" of target atoms. The channeled particle is steered between the rows and prevented from making small impact parameter ( $0.1 \AA$ ) collisions with the row atoms. A good approximation to the motion of the channeled particle moving swiftly past a string of atoms is given by using a Continuum Potential $U(r)$, which is calculated (see Appendix A) by averaging the periodic string potential along the $z$-direction parallel to the string of atoms. $U(r)$ may be expressed in terms of the interatomic potential, $V(P)$, between the particle and a string atom, i.e.,

$$
U(r)=\frac{1}{d} \int_{-\infty}^{\infty} V(\rho) d z
$$

where d is the spacing between string atoms, $r$ is the distance from the particle to the string, and $p^{2}=r^{2}+z^{2}$. $U(r)$ is independent of $z$. Therefore the channeled particle will only experience a force transverse to the string direction, which will tend to repel it towards the centre of the channe1, and so prevent the occurrence of small impact parameter collisions with string atoms. Lindhard gives the Continuum Potential as

$$
U(r)=\frac{2 Z_{1} Z_{2} e^{2}}{4 \pi \epsilon_{0} d} \cdot \xi\left(\frac{r}{a}\right),
$$

with the screening function

$$
\xi\left(\frac{r}{a}\right)=\frac{1}{2} \ln \left(\frac{c^{2} a^{2}}{r^{2}}+1\right)
$$

where a is the Thomas-Fermi screening length of the ion-atom interaction, i.e.,
$a=0.8853 \cdot a_{0}\left(Z_{1}^{2 / 3}+z_{2}^{2 / 3}\right)^{-1 / 2}$
where $a_{0}$ is the Bohr radius, and
C is a fitting parameter for the screening;
$C=\sqrt{3}$ is found to give a good over-all fit.

## I. 3 CONSERVATION OF TRANSVERSE ENERGY

If inelastic energy losses are neglected, the total energy, E, of a channeled particle is conserved and, within the continuum potential approximation, the velocity component $v_{z}$ is constant. Therefore we may simply consider the motion in the plane transverse to the channel axis.

$$
\begin{equation*}
E=K_{\|}+K_{\perp}+U(r)=\text { constant } \tag{I.1}
\end{equation*}
$$

where $K_{\|}$is the component of kinetic energy parallel to the string,
$K_{\perp}$ is the component of kinetic energy perpendicular to the string, and $U(r)$ is the potential energy of the particle. Since $V_{Z}$ is constant, $K_{\|}$is constant. Therefore $K_{\perp}+U(r)=$ constant, i.e., the total energy in the plane transverse to the atom string, $E_{\perp}$, is constant throughout the motion,

$$
\begin{equation*}
E_{\perp}=K_{\perp}+U(r) \tag{1.2}
\end{equation*}
$$

## I.4. CRITICAL TRANSVERSE ENERGY, RANDOM AND CHANNELED TRAJECTORIES, RANDOM FRACTION.

The Continuum Potential approximation breaks down when the channeled particle approaches close enough to the atom row to begin to experience significant deflection from individual atoms. Thus the region of validity of this approximation can be found by demanding that, at the minimum distance of approach, the repulsion of a channeled particle from the string is due to the cumulative effect of scattering by many atoms. The distance travelled along the channel, during the time taken for a collision with the string, is required to be large compared with d. Lindhard uses this condition to find the Continuum Potential approximation to be valid for channeled particles having

$$
E_{\perp}<E \psi_{1}^{2}
$$

where $\psi_{1}=\left(\frac{2 Z_{1} Z_{2} e^{2}}{4 \pi \epsilon_{0} d E}\right)^{1 / 2}$,
and $E$ is the total energy of the particle. If a particle has approximately

$$
E_{\perp} \geqslant E \psi_{1}^{2} \quad \text { or } \psi \geqslant \psi_{2}
$$

where $\psi$ is the instantaneous angle a particle makes with the channel axis, then its trajectory is such that it will feel individual atoms in the string, undergo close-encounter collisions and be scattered out of the channel. Once outside the channel, the particle will interact with the atoms as though the crystal is an amorphous material having a random distribution of atoms. Lindhard therefore calls $E \psi_{2}^{2}$ and $\psi_{1}$ the Critical Transverse Energy, $E_{\perp_{c}}$, and the Critical Angle, $\Psi_{c}$, respectively. He uses these values to differentiate between particles which have Channeled

Trajectories $\left(E_{\perp}<E_{\perp_{C}}\right)$ and those which have Random Trajectories $\left(E_{\perp} \geqslant E_{\perp_{C}}\right)$. When a beam of particles is incident on a channel axis, then for a particular depth in the crystal, the Random Fraction is the ratio of the number of particles having random trajectories (at that depth) to the number of particles incident on the crystal. Small impact parameter collisions ( << a) with string atoms are forbidden for channeled particles, but allowed for random beam particles.

## I. 5 DECHANNELING

In the Continuum Potential approximation, transverse energy is conserved and so the Random Fraction of the beam would be expected to remain constant with depth. However, it is found experimentally that the Random Fraction increases with depth. The implication is that a particle in the Channeled beam ( $E_{\perp}<E \psi_{2}^{2}$ ) at depth $z$ somehow increased its energy as it moved down the channel, until at a depth $z^{\prime}\left(z^{\prime}>z\right), E_{\perp}=E \psi_{2}^{2}$ and the particle made the transition to the random beam. This process of transition from the channeled beam to the random beam is known as Dechanneling.

## I. 6 THE DIFFUSION IN TRANSVERSE ENERGY

The increase in transverse energy was attributed to multiple scattering of the channeled particles by the vibrating target nuclei, electrons and defects. Particles having transverse energy between $\mathrm{E}_{\perp}$ and $E_{\perp}+d E_{\perp}$ are uniformly distributed across their accessible area in transverse plane. As this group of particles moves down the channel, each particle will experience somewhat different multiple (and inelastic)
scattering. Hence, at a larger depth in the crystal, there will be a spread in transverse energy within this group of particles. This spreading, or diffusion, in transverse energy led to the formulation of a Diffusion Equation to describe the change in the distribution of transverse energy and to calculate the Random Fraction as a function of depth ${ }^{14,15}$. The Diffusion Equation has proved difficult to solve numerically.
I. 7 THE STEADY INCREASE IN TRANSVERSE ENERGY (SITE) APPROXIMATION

If dechanneling is to be studied for depths less than a few microns, the calculations may sometimes be simplified by using the SITE approximation, in which diffusion in transverse energy is neglected ${ }^{16-19}$. From (I.2), $E_{\perp}=K_{\perp}+U(r)$ or

$$
\begin{equation*}
E_{\perp}=E \psi^{2}+U(r) \tag{I.3}
\end{equation*}
$$

where $E$ is the total incident energy of the particle and
$\psi$ is the instantaneous angle of the particle's trajectory with the channe1 direction.
Then the average change in transverse energy with depth $\left\langle\frac{d E_{\perp}}{d z}\right\rangle$, averaged over the accessible area in the transverse plane, for particles of transverse energy $E_{\perp}$, is given by

$$
\begin{equation*}
\left\langle\frac{\mathrm{dE} \perp}{\mathrm{dz}}\right\rangle=\mathrm{E}\left\langle\frac{\mathrm{~d} \psi^{2}}{\mathrm{dz}}\right\rangle+\left\langle\psi^{2} \frac{\mathrm{dE}}{\mathrm{dz}}\right\rangle+\left\langle\frac{\mathrm{dU}(\mathrm{r})}{\mathrm{dz}}\right\rangle \tag{I.4}
\end{equation*}
$$

where $E\left\langle d \psi^{2} / d z\right\rangle$ is the average increase in $E_{\perp}$ with depth due to the multiple scattering by nuclei, electrons and defects, if present. In a well-ordered crystal, defect scattering is neglected, and

$$
E\left\langle\frac{d \psi^{2}}{d z}\right\rangle=\left\langle\left(\frac{d E_{\perp}}{d z}\right)_{n}\right\rangle+\left\langle\left(\frac{d E_{\perp}}{d z}\right)_{e}\right\rangle
$$

$\left\langle\psi^{2} \frac{d E}{d z}\right\rangle$ is the average decrease in $E_{\perp}$ with depth due to energy loss from inelastic interactions with electrons (damping term), and
$\left\langle\frac{d U(r)}{d z}\right\rangle=0$, since $U(r)$ is independent of $z$.
Björkqvist ${ }^{16}$ uses Lindhard's analysis to calculate the terms in (I.4) as a function of transverse energy for 2.0 MeV protons incident on the $\langle 100\rangle$ direction in tungsten and for 1.5 MeV protons on the $\langle 111\rangle$ in silicon, see Fig. I.1(a). This Figure shows that channeled particles, which have high transverse energies at the crystal surface, also have high $\left\langle\frac{\mathrm{dE} \mathrm{L}_{\perp}}{\mathrm{dz}}\right\rangle$ values and hence will be dechanneled at shallow depths. The assumption is made that, for these particles, diffusion in transverse energy is small enough to be neglected and that all particles incident on the crystal surface with a transverse energy $E_{\perp}$ will be dechanneled at the same depth below the surface. This is the basis of the SITE approximation.

## I. 8 DECHANNELING MEASUREMENTS IN WELL-ORDERED SINGLE CRYSTALS

Dechanneling measurements have been made for several well-ordered single crystals, e.g., silicon, tungsten, tantalum and, to a lesser extent, gold. In a typical study, dechanneling was investigated as a function of temperature, axial direction and particle type. Calculations, in which dechanneling by defects is presumed to be negligible, have been made using either the SITE approximation or with the diffusion in transverse energy included. Figure I.1(b) shows that agreements between the SITE calculations and the experimental results obtained by Foti et al. ${ }^{18}$ for protons in silicon is reasonable. Figure I.2(a) shows the work of the Aarhus group with protons on silicon $\langle 110\rangle$. Their calculations using

Figure I. 1(a)

Figure I. 1 (b)

Measured points and calculated (by diffusion(-) and using SITE approximation (- - -)) Random fraction versus depth.

Figure I. 2(b)

2 MeV Protons on $\mathrm{Ta}\langle 111\rangle$

Measured (-) and calculated (- ) by diffusion equation, Random Fraction versus Depth as a function of Temperature.
the SITE approximation ${ }^{15}$ and those considering diffusion ${ }^{23,24}$ are in agreement with each other and in reasonable agreement with experiment at shallow depths. They have also found good agreement between their diffusion calculations and experiment for protons in tungsten as a function of temperature and axial direction, but found discrepancies between measured and calculated values for other materials investigated (iron, niobium, molybdenum, tantalum). The calculated Random Fraction for tantalum was found to be lower than the experimental by between $50 \%$ and $100 \%{ }^{24}$, see Figure I. $2(b)$.

## I. 9 DECHANNELING MEASUREMENTS IN DEFECTED SINGLE CRYSTALS

Dechanneling has also been used to study defected single crystals to obtain the defect concentration as a function of depth (defect concentration profile). This has been done by Picraux ${ }^{2 l}$ using proton beams in silicon and by Pronko ${ }^{20}$, Merkle et al. ${ }^{25}$ at Argonne using $\mathrm{He}^{+}$beams in gold. Picraux, in his analysis, assumed that the defects lay in the channels (as interstitials) and the channeled particles directly interacted with the defects. On the other hand, Pronko assumed that the defects were only slightly off lattice sites, causing strains in the lattice, but did not directly cause backscattering of the channeled beam. The lattice strains, however, produced significant dechanneling by causing perturbations in the continuum potential.

Pronko, using the SITE approximation in a dechanneling analysis, was able to determine the broad features in the across-channel distribution of the misaligned atoms in the strained lattice.

## I. 10 OUTLINE OF THIS THESIS

Extensive theoretical and experimental dechanneling studies have been made for a few well-ordered single crystals, such as silicon and tungsten. To our knowledge, gold has received scant attention, except for some room temperature measurements included in the work of Merkle et al., and Pronko. Furthermore, gold is a particularly suitable element for dechanneling studies because:
(i) it is inert to reactions with the atmosphere, therefore it can be prepared with a relatively clean ordered surface,
(ii) it has a low Debye Temperature ( $170^{\circ} \mathrm{K}$ ), hence one dominant dechanneling mechanism, namely thermal nuclear multiple scattering, (iii) it can be prepared, as a single crystal, in either thin film or in bulk crystal form. Hence, gold can be used in defect dechanneling studies using the electron microscope and Rutherford backscattering.

In this thesis we will examine some aspects of a dechanneling study in gold. The thesis describes:
(i) the preparation of well-ordered gold single crystals, (ii) measurement of dechanneling of $2 \mathrm{MeV} \mathrm{He}^{+}$in gold as a function of temperature and depth, and
(iii) comparison of experimental results with theoretical calculations based upon the SITE approximation.

## RUTHERFORD BACKSCATTERING SPECTRA

In this experiment, measurement of the variation of the Random Fraction of the beam with depth, at various temperatures, is required. The detection technique used must therefore be able to distinguish between the scattering of random and channeled beam particles and to provide a means of measuring the depth at which scattering occurs.

The channeled particle cannot have $E_{\perp}>E_{\perp_{C}}$, where $E_{\perp_{c}}=U\left(r_{c}\right)$ $=E \psi_{1 / 2}^{2} \cdot \ln \left(\frac{c^{2} \partial^{2}}{r_{c}^{2}}+1\right), r_{c}$ is the closest distance of approach a channeled particle can have with the centre of the string of atoms and is approximately equal to the Thomas-Fermi screening parameter $a$.

On the other hand, random particles are not steered away from the string atoms and can experience small impact parameter collisions with a probability equal to that for an amorphous target. Rutherford Backscattering is the name given to the collision between a particle and a target atom, when the particle penetrates to a distance very much less than "a" from the nucleus of a target atom. For example, a 2.0 MeV He particle making a head-on collision with a gold target atom approaches to 0.01a from the gold nucleus. Consequently, Rutherford Backscattering (R.B.S.) from a string atom is forbidden for channeled particles, but allowed for random particles. Furthermore, the energy of a backscattered particle leaving the target is a measure of the depth of the scattering below the crystal surface.

Rutherford Backscattering, therefore, is a means of distinguishing between random and channeled particles and, by measuring the ratio of aligned and non-aligned (random) yields from a crystal, the random fraction as a function of depth is determined ${ }^{26}$. This technique has been used in this work.

## II. 1 KINEMATICS

Figure II. 1 represents an elastic collision, in laboratory co-ordinates, between a moving atom, of mass $\mathrm{M}_{1}$, and a stationary target atom, of mass $M_{2}$. It can readily be shown, using the conservation of energy and of linear momentum, that $E_{1}=k^{2} E_{0}$
where $k=\frac{M_{1} \cos \theta_{1}}{M_{1}+M_{2}}+\left[\left\{\frac{M_{1} \cos \theta_{1}}{M_{1}+M_{2}}\right\}^{2}+\frac{M_{2}-M_{1}}{M_{1}+M_{2}}\right]^{1 / 2}$
for $M_{2}>M_{1}$.

## II. 2 R.B.S. ENERGY SPECTRUM

Figure II. 2 shows the beam-target geometry for Rutherford Backscattering. The incident beam consists of particles of mass $M_{1}$ and energy $E_{0}$ and the target atoms have mass M2. Particles backscattered at a depth $x$ into a detector located at an angle $\theta_{1}$, leave the target with an energy $E_{1, x}$. $\mathrm{E}_{1}$ is measured by a semiconductor detector and the distribution in $\mathrm{E}_{1}$ is recorded by a multichannel analyser. The distribution in $\mathrm{E}_{1}$ is called the R.B.S. energy spectrum.

Figure II. 1

Figure II. 2

## II. 3 THE RANDOM SPECTRUM

For the case when the crystal target is not aligned with the beam, all particles have random trajectories and the R.B.S. spectrum is called the Random Spectrum.

## II.3.1 DEPTH SCALE FOR RANDOM SPECTRUM

During their passage through the crystal, the particles lose energy by excitation and ionisation of the target atoms. The rate of energy loss is given by the stopping power, S(E). So, particles scattered at a depth $x$ have a backscattered energy $\mathrm{E}_{1, \mathrm{x}}$, as recorded by the detector, given by:

$$
\begin{equation*}
E_{1, x}=k^{2}\left(\theta_{1}\right) \cdot\left[E_{0}-\int_{B}^{B} S(E) \cdot d l\right]-\int_{B}^{C} S(E) d l \tag{II.2}
\end{equation*}
$$

where the first line integral is along the incoming path and the second along the outgoing path. This expression enables one to make an energy-to-depth conversion ${ }^{27}$.
II.3.2 THE SHAPE OF THE RANDOM SPECTRUM

Assuming that single scattering occurs, the number of particles, $d N$, scattered into the detector from a small depth interval of thickness $d x$ located at a depth x below the crystal surface, see Figure II. 3 , is given by:

$$
\begin{equation*}
d N=N \cdot \eta \cdot d x \cdot d \Omega \cdot \frac{d G}{d \Omega} \tag{II.3}
\end{equation*}
$$

where $d \Omega$ is the solid angle subtended by the detector,
n is the number of atoms per unit volume in the crystal,
$N$ it the total number of particles incident on the crystal, and $\frac{d G}{d \Omega}$ is the Rutherford differential scatteringcross-section, given by:

$$
\begin{equation*}
\frac{d G}{d \Omega}=\left(\frac{Z_{1} Z_{2} e^{2}}{2 \cdot 4 \pi \epsilon_{0}} \cdot \frac{1}{2 E}\right)^{2} \cdot \frac{1}{\sin 4\left(\theta_{1} / 2\right)} \tag{II.4}
\end{equation*}
$$

i.e., $\frac{d G}{d \Omega} \propto \frac{1}{E^{2}}$, where $E$ is the mean energy of beam particles in the interval dx.

If $\mathrm{dE}_{1}$ is the range in values of $\mathrm{E}_{1}$ of particles backscattered from the depth interval dx, then the Random (Energy) Spectrum refers to the variation of $\frac{d N}{\mathrm{dE}_{1}}$ with $\mathrm{E}_{1}$ (see Figure II.4) where (II.3) now becomes:

$$
\begin{equation*}
\frac{d N}{d E_{1}}=N \cdot n \cdot d x \cdot d \Omega \cdot \frac{d G}{d \Omega} \cdot \frac{1}{d E_{1}} \tag{II.5}
\end{equation*}
$$

Therefore the Random Spectrum shape is determined by the variation of $\frac{1}{\mathrm{dE}_{1}} \cdot \frac{\mathrm{~d} \sigma}{\mathrm{~d} \Omega}$ with $\mathrm{E}_{1}$. Usually, but not always, $\frac{\mathrm{dN}}{\mathrm{dE}_{1}}$ increases monotonically as $E_{1}$ decreases and exhibits the shape shown in Figure II. 4 . $\mathrm{E}_{1,0}$, the centre of the well-defined high energy edge, equals the energy of beam particles backscattered from the surface of the target and is a function of the mass ratio $M_{1} / M_{2}$ (see equation (II.1)). The slope of the high energy edge gives a measure of the energy (and hence depth) resolution of the detector.

Si Detector

Figure II. 4

## II. 4 NUMERICAL ANALYSIS OF THE RANDOM SPECTRUM

## II.4.1 CALCULATION OF THE DEPTH SCALE

With reference to Figure II.5, we require to find the relationship between the depth of the backscattering event, $x_{m}$ (= max), and the energy of the backscattered particle recorded by the detector, $\mathrm{E}_{1, \mathrm{~m}}$. This is accomplished by the following numerical analysis of equation (II.2).

The depth $\mathrm{x}_{\mathrm{m}}$ is divided into m equal intervals, each of thickness $\Delta \mathrm{x}$. Summing along the incident beam particle path, we have:

$$
\begin{equation*}
E_{0, m}=E_{0,0}-\sum_{j=1}^{m}\left\{S\left(E_{0, j-1}\right) \cdot \Delta x\right\} \tag{II.6}
\end{equation*}
$$

where $\mathrm{E}_{0,0}=$ Beam energy incident on target, and
$\mathrm{E}_{0, \mathrm{~m}}=$ Beam particle energy after penetration to a depth m. $\Delta x$. Summing along the path of the scattered beam particle gives:

$$
\begin{equation*}
E_{1, m}=\varepsilon_{1,0}-\sum_{l=1}^{m}\left\{S\left(\varepsilon_{1, l-1}\right) \cdot \frac{\Delta x}{\cos \theta_{1}}\right\} \tag{II.7}
\end{equation*}
$$

where

$$
\begin{equation*}
\varepsilon_{1, s}=\varepsilon_{1,0}-\sum_{p=1}^{5}\left\{S\left(\varepsilon_{1, p-1}\right) \cdot \frac{\Delta x}{\cos \theta_{1}}\right\} ; s \neq 0 \tag{II.8}
\end{equation*}
$$

$$
\begin{equation*}
\varepsilon_{1,0}=k^{2} \cdot E_{0, m} \tag{II.9}
\end{equation*}
$$

Equations (II.6) to (II.9) have been used to calculate the relationship between $x_{m}$ and $E_{1, m}$, using a value of $\Delta x$ which gives satisfactory convergence.

## II.4.2 CALCULATION OF THE SHAPE OF THE RANDOM SPECTRUM

The multichannel analyser used to record the energy spectrum is characterised by a relationship between back-scattered energy, $E_{1, m}$, and the analyser channel number, $C_{m}$. I.e.,

$$
E_{1, m}=\Delta E_{1} \cdot C_{m}+b
$$

where $\Delta E_{1}$ is the energy width of each channel.
Let $\langle C\rangle_{\mathrm{m}}$ be the mean channel number for particles backscattered from the m-th depth interval, hence

$$
\langle C\rangle_{m}=1 / 2\left(C_{m}+C_{m-1}\right) .
$$

Let $\langle\Delta N\rangle_{m}$ be the number of counts per channel at channel $\langle C\rangle_{m}$, hence

$$
\langle\Delta N\rangle_{m}=\text { constant }, \frac{1}{\left\langle E_{0}\right\rangle_{m}^{2}} \cdot \frac{1}{\left(C_{m-1}-C_{m}\right)},
$$

where $\left\langle\mathrm{E}_{0}\right\rangle \mathrm{m}$ is the mean energy of an incident beam particle in the moth interval, i.e.,

$$
\left\langle E_{0}\right\rangle_{m}=1 / 2\left(E_{0, m-1}+E_{0, m}\right) .
$$

A plot of $\langle\Delta N\rangle_{m}$ versus $\langle C\rangle_{m}$ represents the calculated random (energy) spectrum which is compared directly to the measured random spectrum by normalising the two plots at channel $C_{S}$, just behind the surface edge (see Figure II.6).

Figure II. 6.
Rand om Spectra. Calculated spectrum (- - -) normalized to measured spectrum (-) near front edge. Two measured thin film spectra are also shown, displaying tails not predicted by single Rutherford scattering theory.

## II.4.3 COMPARISON OF MEASURED AND CALCULATED RANDOM SPECTRA

Experimental random spectra have been taken for $2 \mathrm{MeV} \mathrm{He}{ }^{+}$on gold. A variety of targets have been used, including thin film and bulk specimens in poly-crystalline and in single crystal form. The single crystal specimens were continuously rotated in order to reduce any channeling effects to essentially negligible amounts. All these measured spectra were found to have the same shape to within approximately $2 \%$. The mean value of these measured spectra is plotted in Figure II.6, and the calculated spectrum normalised to this mean measured spectrum. Two measured spectra from thin films are also shown.

The calculated spectrum and the depth scale, calculated according to the analysis in sections II.4.2 and II.4.1, assume single scattering and use an empirical stopping power function $S(E)$ given in the recent comprehensive compilation by Ziegler and Andersen ${ }^{28}$.

The difference between the measured and calculated spectra appears to be a consequence of the effects producing the low energy "tails" which are evident in the measured thin film spectra. The origin of the low energy tails is uncertain, but may well be due to particles entering the detector as a result of more than one large-angle scattering. Figure II. 6 shows that, at a depth of $6000 \AA$, the difference between the measured Random Spectrum and that calculated assuming s ingle Rutherford scattering is approximately 6\%. Our assumption that single Rutherford scattering is the predominant mechanism for backscattering of $2 \mathrm{MeV} \mathrm{He}{ }^{+}$from gold and the use of the Ziegler and Andersen stopping power data would appear to be valid. However, for 1 MeV protons in gold, a difference of $15 \%$ or greater between calculated and measured Random Spectra was found at depths greater
than 15,000 A. In the absence of further data, this leads to corresponding uncertainties in the determination of the Random Fraction from the R.B.S. spectra of 1 MeV protons from gold. Consequently, this thesis is restricted to a study of the dechanneling of $2 \mathrm{MeV} \mathrm{He}^{+}$in gold.

## II. 5 THE ALIGNED SPECTRUM AND THE RANDOM FRACTION

The aligned spectrum refers to the backscattered energy spectrum taken with the crystal axis precisely aligned with the beam direction. If the crystal has no displacement defects, from which the channeled beam can backscatter, then only the random fraction of the beam can undergo backscattering. In this case, assuming single (R.B.S.) scattering and that the same energy to depth scale conversion applies to both the random and aligned spectra, then the Aligned Yield, $d N^{\prime}$, is given by:

$$
\begin{equation*}
d N^{\prime}=N^{\prime} \cdot n \cdot d x \cdot d \Omega \cdot d G \tag{II.10}
\end{equation*}
$$

where $N^{\prime}$ is the number of particles in the random beam incident on the depth interval of thickness $d x$ at a distance $x$ below the crystal surface. The Random Fraction, $\mathcal{X}$, at that depth is defined as $N^{\prime} / N$, where $N$ is the total number of particles incident on the crystal. Hence, the ratio of the Aligned Yield to the Random Yield for that depth interval is given by:

$$
\frac{d N^{\prime}}{d N}=\frac{N^{\prime} \cdot n \cdot d x \cdot d \Omega \cdot d \sigma / d \Omega}{N \cdot n \cdot d x \cdot d \Omega \cdot d \sigma / d \Omega}=\frac{N^{\prime}}{N}=\chi(x)
$$

using (II.3) and (II.10), and so the Random Fraction as a function of depth can be extracted from the measured Aligned and Random Spectra.

The general features of aligned spectra are shown in Figure II.7; a random spectrum is included for quantitative comparison. The increase (with increasing depth) of the aligned yield, and hence the dechanneling rate and the random fraction, with increase in temperature and defect concentration is illustrated schematically.

## II.5.1 SURFACE PEAK IN THE ALIGNED SPECTRUM

The incident beam does not yet experience the channeling effect, at the surface, therefore it is not steered away from the surface atoms. Hence the aligned beam scatters from the surface atoms with normal probability and a normal (random) yield is always obtained from the surface atoms. The surface peak in the aligned spectrum is due to backscattering from any disordered gold atoms at the surface and/or the gold atoms at the ends of the atomic strings, the latter effect being temperature-dependent.

The number of atoms per unit area at the surface contributing to the surface peak can be calculated using the surface peak yield and the random yield from the surface region. 29

If $Y_{S A}$ is the surface peak yield in the aligned spectrum and $Y_{S R}$ is the yield in the random spectrum from a surface element of thickness $d x$, then, for the same number of incident beam particles, $N$,

$$
Y_{S A}=N \cdot n^{\prime} \cdot d x^{\prime} \cdot d \Omega \cdot \frac{d G^{\prime}}{d \Omega},
$$

and

$$
Y_{S R}=N \cdot n \cdot d x \cdot d \Omega \cdot \frac{d G}{d \Omega},
$$

where $n^{\prime} d x^{\prime}$ is the number of atoms per unit area in the surface which can backscatter the aligned beam, and

a) Pand om Spectrum
b) Aligned Spectrum, crystal with defects, room temperature
c) Aligned Spectrum, crystal without defects, room temperature
d) Aligned Spectrum, crystal without defects, low temperature.
$\frac{d G^{\prime}}{d \Omega}=\frac{d \boldsymbol{G}}{\mathrm{~d} \Omega}$, since backscattering occurs at the same depth (and hence energy) in each case.

Hence

$$
n^{\prime} \cdot d x^{\prime}=\frac{y_{S A}}{y_{S R}} \cdot n \cdot d x
$$

A1so

$$
n \cdot d x=\frac{n \cdot \Delta E}{k^{2} \cdot S_{0}+S_{1} / \cos \theta_{1}}
$$

where $S_{0}, S_{1}$ are the stopping powers of the incident and backscattered beam respectively and $\Delta E$ is the difference in energy of particles from the front and rear surfaces of dx .27

For small values of dx , and with $\theta_{1}=150^{\circ}$ and $\mathrm{k}^{2}=0.92696$ for $\mathrm{He}^{+}$on gold, then $\quad k^{2} S_{0}+S_{1} / \cos \theta_{1} \approx 2 S_{0}$.

Therefore

$$
n^{\prime} d x^{\prime}=\frac{Y_{S A}}{Y_{S R}} \cdot \frac{n \cdot \Delta E}{2 S_{0}}
$$

$Y_{S A}, Y_{S R}$ and $\Delta E$ can be measured and $S_{0}$ taken from the tables of Ziegler and Andersen. 28

From the observed variation of $n$ 'dx' with temperature, the number of disordered gold atoms per unit area at the surface can be deduced.

## II.5.2 MINIMUM YIELD, $\chi$ min

$X$ min is the value of the Aligned Fraction in the surface region. In a well-ordered crystal, it is essentially the fractional area for which channeled trajectories are not possible when a beam is aligned with a channel axis. Within this area, the initial transverse energy is greater than the critical value $\mathrm{E}_{\perp_{c}}$.

Lindhard ${ }^{14}$ has approximated $\chi_{\text {min }}$ by:

$$
x_{\min } \approx \text { n.d. } \pi \cdot\left(a^{2}+\rho^{2}\right)+x_{3}
$$

where n is the number of atoms per unit volume in the crystal,
d is the interatomic spacing along the string,
a is the Thomas-Fermi screening length,
$\rho$ is the r.m.s. thermal vibrational amplitude at the crystal temperature.
$x_{3}$ refers to the component of the Random Fraction due to single Rutherford scattering of particles in the aligned beam through angles greater than $\Psi_{1}$ by atoms in the surface disorder layer. ${ }^{14}$

$$
x_{3} \approx \frac{n \cdot \Delta z \cdot \pi \cdot z_{1}^{2} \cdot z_{2}^{2} \cdot e^{4}}{\left(4 \pi \epsilon_{0}\right)^{2} \cdot E^{2} \Psi_{1}^{2}}
$$

Better agreement between experimental and calculated $\chi_{\text {min }}$ values has been obtained by Barrett ${ }^{39}$, who used Monte Carlo calculations to obtain the expression,

$$
x_{\text {min }}=\text { n.d. } \pi .\left(3( \pm 0.2) p^{2}+0.2( \pm 0.1) d^{2}\right) .
$$

This expression generally gives good agreement with experimental values obtained from crystals with minimal surface disorder.

## CHAPTER THREE

THE STEADY INCREASE IN TRANSVERSE ENERGY (SITE) APPROXIMATION

#### Abstract

If $\left\langle\frac{d E}{d z}\right\rangle$ increases rapidly with $E_{\perp}$, then particles having high initial transverse energy, $\mathrm{E}_{\perp_{\mathrm{O}}}$, will be dechanneled at shallow depths, before diffusion (i.e., spread) in their transverse energy becomes appreciable. In such cases, diffusion in $E_{\perp}$ can be neglected and we assume that the transverse energy of the particle increases steadily with depth, such that $\left\langle\frac{\mathrm{dE}}{\perp} \mathrm{dz}^{\mathrm{dz}}\right\rangle=\left(\frac{\mathrm{dE}}{\mathrm{\perp}} \mathrm{H}\right)$. This is the basic assumption of the SITE approximation. ${ }^{14}$ We have calculated $\left\langle\frac{d E_{10}}{d z}\right\rangle$ versus $E_{1_{0}}$ for $2 \mathrm{MeV} \mathrm{He}{ }^{+}$in $\langle 110\rangle$ gold, see Figure III.1, using the analyses of Lindhard ${ }^{14}$ and Fotil8. It can be seen from this figure that the criterion for using the SITE approximation is fulfilled in this case.

The depth $z^{\prime}$, at which a particle having initial transverse energy $\mathrm{E}_{\perp_{0}}$ ' will be dechanneled, is given by:

$$
z^{\prime}=\int_{E_{1_{0}^{\prime}}}^{E_{\perp_{c}}} \frac{d E_{\perp}}{\left(d E_{\perp} / d z\right)}
$$

where $E_{\perp_{c}}$ is the critical transverse energy. Particles having $E_{\perp_{0}}>\mathrm{E}_{\Lambda_{0}}{ }^{\prime}$ will also be in the random beam at depth $z^{\prime}$. Therefore,

$$
\int_{E_{1_{0}^{\prime}}^{\infty}}^{\infty} p\left(E_{1_{0}}\right) d E_{1_{0}}
$$

will give the Random Fraction of the beam at depth $z^{\prime}$, where $p\left(E_{\perp_{0}}\right)$ is the initial transverse energy probability distribution. By selecting different $\mathrm{E}_{\perp_{0}}{ }^{\prime}$ values and using this procedure, the Random Fraction as a function of depth can be calculated.

The following outline of the SITE approximation is due to Lindhard ${ }^{14}$ and Foti et al ${ }^{18}$

Figure III. 1

III. 1 THE INITIAL TRANSVERSE ENERGY DISTRIBUTION

If the incident beam is precisely aligned with a channel axis and we neglect the effect of scattering by disordered surface atoms, then the initial transverse energy $E_{\perp_{0}}$, measured with respect to that at the centre of the channel, is given by

$$
\begin{equation*}
E_{\perp_{0}}=U(r)-U\left(r_{0}\right) \tag{III.1}
\end{equation*}
$$

where $r$ is the distance (in the transverse $p l a n e$ ) of the point of impact from the centre of the atomic string,
$r_{0}$ represents the distance from the string to the channel centre, and $\pi r_{0}{ }^{2}$ is approximately equal to the area per string projected perpendicular to the string direction.

If $n$ is the number of atoms per unit volume in the crystal and $d$ is the interatomic spacing along the string, then

$$
n \cdot d \cdot \pi r_{0}^{2}=1
$$

$U(r)$ is the standard Lindhard continuum potential

$$
\begin{equation*}
U(r)=\frac{z_{1} z_{2} e^{2}}{4 \pi \epsilon_{0} d} \cdot \ln \left(\frac{c^{2} a^{2}}{r^{2}}+1\right) \tag{III.2}
\end{equation*}
$$

The probability that a particle has an initial transverse energy between $E_{\perp_{0}}$ and $E_{\perp 0}+\mathrm{dE}_{\perp_{0}}$ is equal to the probability that it enters the crystal between $r$ and $r+d r$ (in the transverse $p l a n e$ ) from the centre of a string, see Figure III.2.

Hence the Initial Transverse Energy Distribution, $p\left(E_{\perp_{0}}\right)$, is given by:

Figure III. 2

$$
\begin{equation*}
p\left(E_{1_{0}}\right) d E_{10}=\frac{\pi d\left(r^{2}\right)}{\pi r_{0}^{2}}=\frac{2 \pi r d r}{\pi r_{0}^{2}} \tag{III.3}
\end{equation*}
$$

From (III.1), (III.2) and (III.3), it can readily be shown that:

$$
\begin{equation*}
p\left(E_{1_{0}}\right) d E_{1_{0}}=\frac{c^{2} a^{2} \cdot A \cdot 4 \pi \epsilon_{0} d}{r_{0}^{2}} \cdot e^{2 E_{10} / E \psi_{1}^{2}} d E_{1_{0}} e^{2}\left(A \cdot e^{2 E_{10} / E \psi_{1}^{2}}-1\right)^{2} \tag{III.4}
\end{equation*}
$$

where

$$
A=\frac{c^{2} a^{2}}{r_{0}^{2}}+1 \quad \text { and } \quad E \psi_{1}^{2}=\frac{2 Z_{1} Z_{2} e^{2}}{4 \pi \epsilon_{0} d}
$$

III. 2 THE RATE OF CHANGE OF TRANSVERSE ENERGY WITH DEPTH

During the motion of the particle in the channel, its transverse energy is given by:

$$
E_{1}=E \psi^{2}+U(r)-U\left(r_{0}\right)
$$

Hence the average change in transverse energy with depth is given by:

$$
\begin{equation*}
\left\langle d E_{1 / d z}\right\rangle=E\left\langle d \psi^{2} / d z\right\rangle+\left\langle\psi^{2} d E / d z\right\rangle+\langle d U / d z\rangle \tag{III.5}
\end{equation*}
$$

The average is taken over the area in the transverse plane, equal to $\pi\left(r_{0}{ }^{2}-r_{\min }{ }^{2}\right)$, which is accessible to a particle of transverse energy $E_{\perp}$, where

$$
E_{1}=U\left(r_{\min }\right)-U\left(r_{0}\right)
$$

Figure III. 3

It is assumed that particles having transverse energy $\mathrm{E}_{\perp}$ are uniformly distributed over the accessible area, i.e., there is a statistical equilibrium.

We shall consider the case of a perfect crystal, in which the multiple scattering due to disorder defects is therefore zero. Hence the multiple scattering term, $E\left\langle\frac{d \psi^{2}}{d z}\right\rangle$, can therefore be written:

$$
E\left\langle\frac{d \psi^{2}}{d z}\right\rangle=\left\langle\left(d E_{1} / d z\right)_{n}\right\rangle+\left\langle\left(d E_{1} / d z\right)_{e}\right\rangle
$$

where $n$ and e refer to scattering by string atoms (nuclear) and atomic electrons (electronic scattering) respectively.

## III. 3 DAMPING TERM

Lindhard estimates the damping term, $\left\langle\Psi^{2} \frac{d E}{d z}\right\rangle$, to be given by:

$$
\left\langle\psi^{2} d E / d z\right\rangle \approx \beta \frac{E_{1}}{E}\langle d E / d z\rangle
$$

where $\beta \approx 0.5 \rightarrow 1.0$.
We have used, with Björkqvist et al. ${ }^{16}$, the value $\beta=0.5$. Note that $\left\langle\frac{d E}{d z}\right\rangle$ is negative, reflecting the reduction in total energy of the particle as it moves along the trajectory. Consequently, the damping term contributes a reduction to the rate of increase in $E_{\perp}$.

Since $U(r)$ is independent of $z$, then $\left\langle\frac{d U}{d z}\right\rangle=0$. Therefore
(III.5) becomes:

$$
\begin{equation*}
\left\langle d E_{1} / d z\right\rangle=\left\langle\left(d E_{1} / d z\right)_{n}\right\rangle+\left\langle\left(d E_{1} / d z\right)_{e}\right\rangle+0 \cdot 5 \frac{E_{1}}{E}\left\langle d E^{2} / d z\right\rangle \tag{III.6}
\end{equation*}
$$

III. 4 NUCLEAR MULTIPLE SCATTERING

Lindhard considered the deviations from the transverse force $\vec{K}(r)$, corresponding to the continuum potential, which are caused by thermal vibrations of the string atoms and evaluated their scattering effect on channeled particles (of mass $\mathrm{M}_{1}$, velocity v).

The average increase in $E_{\perp}$, due to the thermal vibrations of string atoms, (along a path $\delta z$ ) is estimated to be

$$
\begin{equation*}
\left\langle\delta E_{1}\right\rangle_{n}=\left\langle E_{1 \delta z+z}\right\rangle-E_{1 z}=\left\langle\frac{\sum\left(\delta \vec{p}_{1}\right)^{2}}{2 M_{1}}\right\rangle=\frac{d}{4 E}\left\langle\delta \vec{K}(r)^{2}\right\rangle . \delta z \tag{III.7}
\end{equation*}
$$

where $\delta \overrightarrow{\mathrm{K}}(r)$ is the deviation from $\overrightarrow{\mathrm{K}}(r)$ experienced by the channeled particle as it passes by the thermally-displaced string atom, and $\delta \overrightarrow{\mathrm{P}}_{\perp}$ is the corresponding deviation in transverse momentum due to the displacement. The averaging in (III.7) is taken over the accessible transverse area for particles with that transverse energy, over the possible thermal displacements, and also along the path $\delta$ z.

For small thermal vibrational amplitudes, $r \gg P$, and so (as stated by Lindhard):

$$
\begin{equation*}
\left\langle\delta \vec{K}(r)^{2}\right\rangle=1 / 2 \rho^{2}\left\langle\frac{K^{2}(r)}{r^{2}}+\left(\frac{d K(r)}{d r}\right)^{2}\right\rangle \tag{III.8}
\end{equation*}
$$

where $K(r)=-\partial U / \partial r$
and $U=U(r)-U\left(r_{0}\right)$
Using (III.8), (III.9) and (III.10) in (III.7), the following result is obtained by Foti et al. ${ }^{18}$ :

$$
\begin{align*}
\frac{\left\langle\delta E_{1}\right\rangle_{n}=}{\delta z}= & \frac{\pi \cdot n \cdot Z_{1} \cdot Z_{2} \cdot e^{2} \cdot d \cdot P^{2} \cdot E \psi_{1}^{2}}{E \cdot 4 \pi \epsilon_{0} \cdot C^{2} \cdot \partial^{2} \cdot 2}\left\{\frac{\left(A e^{2 E_{1} / E \psi_{-}^{2}}-1\right)}{A\left(e^{\left.2 E_{1} / E \psi_{1}^{2}-1\right)}\right.}\left(A e^{2 E_{1} / E \psi_{1}^{2}}+2 / 3\right)\right. \\
& \left.\cdot\left(1-\frac{e^{-2 E_{1} / E \psi_{1}^{2}}}{A}\right)^{3}\right\} \tag{III.11}
\end{align*}
$$

III. 5 ELECTRONIC MULTIPLE SCATTERING

Bohr ${ }^{22}$ gives the change in the average square fluctuation in angle, due to electronic collisions, to be:

$$
\begin{equation*}
\delta \Omega_{e}^{2}=\frac{m_{e}}{2 M_{1} E} \cdot S_{e} \cdot R(r) \cdot \delta z \tag{III.12}
\end{equation*}
$$

where $m_{e}$ is the mass of an electron,
$R(r)$ is the electron density at a distance $r$ from the string, corresponding to the solution of a Poisson's Equation using the continuum potential, and
$S_{e}$ is the stopping cross-section per electron and for swift particles, $S_{e}$ is given by the Bethe-Bloch formula:

$$
\begin{equation*}
S_{e}=\frac{4 \pi \cdot Z_{1}^{2} \cdot e^{4}}{m_{e} v^{2}} \cdot \frac{1}{\left(4 \pi \epsilon_{0}\right)^{2}} \cdot L_{e} \tag{III.13}
\end{equation*}
$$

with

$$
\begin{equation*}
L_{e} \approx \ln \left(2 m_{e} v^{2} / I\right) \tag{III.14}
\end{equation*}
$$

and $I$ is the mean ionisation potential of the target atom, $I \approx 10 . \mathrm{Z}_{2} \mathrm{eV}$. Foti et al. ${ }^{18}$ averages $R(r)$ over the accessible area in transverse space and, using (III.12), (III.13) and (III.14), finds:

$$
\begin{align*}
\left\langle\left(d E_{1} / d z\right)_{e}\right\rangle & =E\left\langle\left(\delta \Omega^{2} / \delta z\right)_{e}\right\rangle=\left[\frac{n \cdot Z_{1} \cdot \pi \cdot e^{2} \cdot d}{E \cdot 4 \pi \epsilon_{0}} \cdot \frac{E \psi_{1}^{2}}{2} \cdot \ln \left(\frac{2 m_{e} v^{2}}{10 \cdot Z_{2}}\right)\right. \\
& \left.\cdot\left\{\frac{\left(A e^{2 E_{1} / E \psi_{1}^{2}}-1\right)}{A\left(e^{2 E_{1} / E \psi_{1}^{2}}-1\right)} \cdot\left(1-\frac{e^{-2 E_{1} / E \psi_{1}^{2}}}{A}\right)\right\}\right] \tag{III.15}
\end{align*}
$$

Since all the terms in (III.6) have now been obtained in analytic form, and using the Stopping Power, $\frac{d E}{d z}$, tabulated by Ziegler and Andersen ${ }^{28}$, the calculation of Random Fraction as a function of depth can be made.
III. 6 NUMERICAL CALCULATION OF RANDOM FRACTION AS A FUNCTION OF DEPTH The average square amplitude of atomic vibrations, $\rho^{2}$, in the transverse plane is taken to be $2 / 3$ mean square amplitude, in three dimensions: (see Björkqvist et al. ${ }^{16}$ ) and is calculated using the formula given by Lonsdale ${ }^{30}$ :

$$
\overline{u^{2}}=\frac{4.364 \times 10^{-18}}{\text { A. } \theta} \cdot\left\{\frac{\Phi(x)}{x}+0.25\right\} m^{2}
$$

where $\quad e^{2}=2 / 3 \overline{u^{2}} \quad$ and
$\Phi(x)$ is the Debye function,
$\mathrm{x}=\theta / \mathrm{T}, \theta$ is the Debye Temperature
$\left(\theta_{\mathrm{Au}}=170 \mathrm{~K}\right)$, and T is the temperature in question. $\rho^{2}$ determines the temperature-dependence of
(i) the critical transverse energy, $E_{\perp_{c}}$, where

$$
E_{1_{c}}=\frac{Z_{1} Z_{2} e^{2}}{4 \pi \epsilon_{0} d} \cdot \ln \left(\frac{C^{2} a^{2}}{r_{c}^{2}}+1\right)
$$

and. $r_{c}^{2}=\rho^{2}+a^{2}$, and
(ii) the rate of increase of transverse energy $\left\langle\frac{d E_{\perp}}{d z}\right\rangle$.

The numerical calculation was made in the following way: selected values of $E_{\perp_{0}}$ were obtained by taking successive small decrements of $E_{\perp}$ from $E_{\perp_{c}}$. Consider one value, $E_{\perp_{0}}{ }^{\prime}$,
At the crystal surface

$$
\begin{aligned}
& \text { Total Energy, } E=E_{0} \\
& \text { Transverse Energy, } E_{\perp}=E_{\perp}{ }_{0}^{\prime}
\end{aligned}
$$

At a small depth interval $z$ (intervals of $100 \AA$ were used in the calculation)

$$
\begin{aligned}
& \text { Total Energy, } E=E_{0}-S\left(E_{0}\right) \cdot z=E_{1} \\
& \text { Transverse Energy, } \\
& E_{\perp}=E_{\perp}^{\prime}+\left\langle\frac{d E_{\perp}}{d z}\right\rangle\left(E_{0}, E_{\perp}^{\prime}\right) \cdot z=E_{\perp}^{\prime}
\end{aligned}
$$

where $S(E)$ denotes the Random Stopping Power, $\frac{\mathrm{dE}}{\mathrm{dz}}$.
If $E_{\perp}^{\prime}<E_{\perp_{C}}$, then another depth interval is considered with the energies at the back of the second interval given by:

Total Energy $E=E_{2}=E_{1}-S\left(E_{1}\right) \cdot z$
Transverse Energy $E_{\perp}=E_{\perp}^{\prime}=E_{\perp}^{\prime}+\left\langle\frac{d E_{\perp}}{d z}\right\rangle\left(E_{1}, E_{\perp}^{\prime}\right) \cdot z$
and so on for successive intervals, until $E_{\perp_{n}^{\prime}}^{\prime} \geqslant E_{\perp_{c}}$. $n z$ would then be tabulated and the Random Fraction at $n z, \chi(n z)$ would be calculated from:

$$
\begin{equation*}
x(n z)=\int_{E_{1}^{\prime}}^{\infty} p\left(E_{1_{0}}\right) \cdot d E_{1_{0}}=\frac{A-1}{A e^{2 E_{1_{0}^{\prime}} / E \psi_{1}^{2}-1}} \tag{III.16}
\end{equation*}
$$

which is obtained by integrating equation (III.4).
The measured component of the Random Fraction caused by scattering of the aligned beam in the disordered surface layer, $\mathcal{X}_{3}$, is added to that found from (III.16).

## CHAPTER FOUR

GOLD SINGLE CRYSTAL PREPARATION

The crystals used in our experiments must have a sufficiently low concentration of defects distributed through their bulk so that dechanne1ing by defects is negligible in comparison to that caused by thermally vibrating nuclei and electrons. The crystals must also have minimum surface disorder to minimise the Random Fraction at the surface and to simplify the calculation of the transverse energy distribution of the incident particles.

## IV. 1 EVALUATION OF CRYSTAL QUALITY

The evaluation of crystal quality is made using three complementary experimental techniques:
(a) Laue diffraction of $X$-rays, which is used to assess the average quality of the crystal over a depth of several microns,
(b) diffraction of mono-energetic electrons, used to assess the quality of the surface region to depths up to several hundred Angstroms,
(c) Rutherford backscattering-dechanneling, which can be used to determine the amount of surface disorder and to compare the quality of crystals in terms of their dechanneling rates observed over depths up to several microns.

## IV.1.1 X-RAY DIFFRACTION

An 18 keV beam of continuous X -rays was used in the standard Laue Back-Reflection arrangement. A description of the interpretation of the
diffraction spot pattern can be found in standard X-ray diffraction texts ${ }^{31}$. For a single crystal, each spot in the diffraction pattern can be identified with a reflection from a particular set of planes in the crystal and the pattern may be analysed to determine the orientation of the crystal with the X-ray beam. For our purposes, however, it is sufficient to note that the diffraction spot from a set of planes in a perfect crystal is circular and has a sharp outline and that any deviations from this are produced by crystal defects. The Laue spots obtained from diffraction quality, freshly-cleaved NaCl, purchased from Harshaw Chemical Company, were used as a reference. The shape and sharpness of the diffraction spots from gold crystals were carefully inspected visually and compared with those in the NaCl pattern, see Fig. IV.1(a) and (b). X-ray diffraction patterns obtained from NaCl crystals, overlaid with two micron thick gold films, showed strong absorption of the X-rays. Therefore, X-ray diffraction gives an assessment of gold crystal structural quality averaged over several microns.

## IV.1.2 ELECTRON DIFFRACTION

The McMaster University electron microscope (Phillips EM300) was used in the reflection transmission mode. Monoenergetic electrons ( 80 keV or 100 keV in this case) are incident at a glancing angle to the crystal surface, the orientation of which is adjusted to give a Bragg diffraction pattern on a photographic plate.

The electrons are strongly scattered and only those which are diffracted from planes within a few hundred Angstroms of the surface will emerge again from the crystal surface to form the diffraction pattern. Reflection

Figure IV. 1(a). X-ray diffraction pattern obtained from the reference NaCl crystal.

Figure IV. 1(b). Typical x-ray diffraction pattern from a gold crystal.
electron diffraction therefore permits observation of the structure of the near surface region ${ }^{32}$. Figure IV. 2 shows diffraction photographs taken of the same gold crystal using X-rays and electrons. The surface structure is revealed as polycrystalline (by electrons) and the underlying bulk as a single crystal (by X-rays). In contrast, Fig. IV. 3 shows electron and X-ray diffraction patterns from a gold sample which is a single crystal throughout. The presence of Kikuchi lines, a complex network of pairs of dark and bright lines, superimposed on an electron diffraction spot pattern is an indication of a high quality monocrystalline region near the crystal surface ${ }^{33}$.

## IV.1.3 RUTHERFORD BACKSCATTERING-DECHANNELING

Crystals, which exhibited good X-ray and electron diffraction patterns, were examined further using $\mathrm{MeV} \mathrm{He}^{+}$Rutherford Backscattering. Aligned and Random Spectra were taken at room temperature for each crystal. Three spectral parameters have been used in the assessment of crystal quality.

The area of the surface peak in the Aligned Spectrum gives a quantitative measurement of the areal density of displaced gold atoms at the crystal surface ${ }^{29}$.

The Aligned Fraction at the surface, $X_{\text {min }}$, and the rate of increase of random fraction with depth, the dechanneling rate, both increase with crystal defect density and have been used to make the final selection of crystals. Details of these spectra are described in Chapter Two and a comparison of the room temperature aligned spectra for different crystals is shown in Chapter Five.

Figure IV. 2(a). Electron diffraction pattern revealing the polycrystalline structure of the surface of this gold crystal.

Figure IV. 2(b). X-ray diffraction pattern obtained from the same crystal used to obtain the electron diffraction pattern above. Here, the underlying bulk is shown to be single crystal.

Figure IV. 3(b). X-ray diffraction pattern of the gold sample used in Figure IV. 3(a) showing the underlying bulk to be single crystal.

## IV. 2 PRODUCTION AND PREPARATION OF SINGLE CRYSTALS

## IV.2.1 EPITAXIAL FILMS

Initially, the gold single crystals were produced as thin films, approximately one micron thick, epitaxially grown on NaCl substrates. This was achieved by evaporation of $99.99 \%$ pure gold wire on to the freshly-cleaved, in air [100] face of a NaCl substrate. The substrate was held at a temperature of $\sim 450^{\circ} \mathrm{C}$ in a vacuum of better than $10^{-5}$ Torr. and the gold condensed on the substrate at a rate of $\sim 20 \AA / \mathrm{s}$. Approximately $50 \%$ of the gold crystals grown in this fashion showed a single orientation with the substrate, but they generally had diffuse spots in their $X$-ray patterns, see Figure IV.4. In addition, Rutherford backscattering measurements showed that these crystals had $X_{\text {min }}$ values between $10 \%$ and $15 \%$, in comparison with the theoretical value for a defect-free gold crystal of $\sim 2.5 \%$. In order to reduce the concentration of defects in the epitaxial gold films, these films must be annealed. This required the development of difficult techniques to remove the film intact from the NaCl substrate and to support the film during annealing. Therefore it was decided to abandon this approach to the production of gold single crystals and turn attention to the problem of polishing and annealing of crystals sectioned from bulk gold single crystals.

## IV.2.2 BULK CRYSTALS

Bulk gold single crystals were obtained from Chalk River Nuclear Laboratories ${ }^{34}$. They were $7-10 \mathrm{~mm}$ in diameter and had been cut, by spark erosion, into slices of thickness between 2 and 4 mm . All samples had been mechanically polished with fine powders of $0.25 \mu \mathrm{~m}$ diameter.

Figure IV. 4(a). X-ray diffraction pattern of epitaxial Au crystal having more than one preferred orientation.

Figure IV. 4(b). X-ray diffraction pattern of an epitaxial Au crystal having one preferred orientation, but having diffuse spots.

X-ray diffraction patterns were then taken of these gold crystals, as received, which showed a dense diffuse background and faint streaks, see Figure IV.7(a). The crystals were thus assumed to have heavily damaged surface regions extending several microns below their outer faces.

The further treatment of the crystal, which was required in order to remove the dense surface disorder and any defects in the underlying bulk, was developed empirically. Metal crystals, such as tungsten and copper, suitable for channeling studies have been produced at C.R.N.L. by using the following sequence of stages in preparation: annealing, cutting, mechanical polishing, vibratory polishing, and finally electropolishing. However, this preparation was found to be totally inadequate for gold crystals ${ }^{35}$. Gold is exceptionally soft and would sustain deep mechanical damage during cutting and mechanical polishing. Thus, a further annealing stage may be required after polishing.

It was found that a combination of electropolishing and annealing in the final stages of preparation produces well-ordered gold single crystals in which defect dechanneling at room temperature appears to be negligible. A description of the electropolishing and annealing stages, used in this project, follows.

## IV.2.3 ELECTROPOLISHING PROCEDURE

A diagram of the apparatus used is shown in Figure IV.5. The standard electrolyte for gold ${ }^{36}$ was used ( 22 g chromic acid: 135 c.c. acetic acid:7 c.c. water). The correct operating state of the polisher was determined by observing the crystal surface topography produced as a function of the cell voltage. Figure IV. 6 shows the rough surface due to

## Figuxe IV. 5

The Electropolishing Rig

chemical etching when the cell voltage was too low and the smooth surface produced by electropolishing when the cell voltage was at 22 volts (the operating voltage). The polishing rate was found to be approximately 35 microns per hour and approximately 50 microns was normally removed. Figure IV. 7 shows the X-ray diffraction patterns taken before and after electropolishing. The polishing removes the dense surface disorder and leaves a single crystal with a significant defect density as evidenced by the diffuse, structured, Laue X-ray spots, see also Figure IV.9.(a), (b) and (c). The structure in the spots is assumed to be due to extended defects, for example, edge dislocations and low-angle tilt boundaries.

## IV.2.4 ANNEALING MECHANISMS

The mechanisms involved in annealing are not yet fully understood ${ }^{37}$. However, some relevant information is available concerning defects in crystals ${ }^{38}$ :
(a) extended defects, such as edge dislocations and low-angle tilt boundaries, are mobile at high temperatures (however, dislocations moving in different planes can interact at the intersection of these planes and become immobile or sessile),
(b) the equilibrium concentration of simple defects, such as monovacancies, is related to the crystal temperature by a Boltzmann factor, i.e., $C_{1 V}$ is proportional to $e^{-E_{1 V} / k T}$, where $E_{1 V}$ is the energy required to create a monovacancy,
(c) the creation of a vacancy requires the proximity of a "sink" for the de-sited atom, such as a crystal surface, grain boundary, tilt boundary or edge dislocation.

Figure Iv. 6(a). Rough surface caused by chemical etching. (One centimetre on the photograph represents approximately 35 microns on the gold surface.)

Figure IV. 6(b). Smooth surface produced by electropolishing.

Figure IV. 7(a). X-ray pattern before electropolishing.

Figure IV. 7(b). X-ray diffraction pattern after electropolishing.

If the temperature of the gold crystal is held near its Melting Point $\left(1063^{\circ} \mathrm{C}\right)$ for a long time, some of the extended defects will become mobile and move out to the crystal surface. It is suggested that the large number of atoms re-sited in sessile extended defects at this temperature may cause a re-arrangement of the configuration of these defects into smaller, more mobile defects, such as divacancies and trivacancies.

After annealing, the temperature of the annealing system is reduced very slowly, so that the system retains thermal equilibrium and the concentrations of the simple defects will be the equilibrium values appropriate to the instantaneous temperature.

## IV.2.5 ANNEALING PROCEDURE

A photograph of the vacuum annealing chamber is shown in Figure IV. 8. The thermocouples were calibrated against the Melting Points of gold, silver and lead. The Ultra High Vacuum pumping system kept the pressure below $10^{-7}$ Torr. throughout annealing. The temperature reduction was automated using electric motors.

Figure IV. 9 shows a sequence of X-ray diffraction photographs which were taken during the development of the annealing procedures. (This crystal had received some electropolishing at C.R.N.L.). Rather little improvement in single crystal quality is evident following the 14 hour anneal at $665^{\circ} \mathrm{C}$. Clearly shown is the significant improvement produced by the $1000^{\circ} \mathrm{C}$ anneal and the benefit of prolonged annealing (60 hours versus two hours) at this temperature.

Figure IV. 9(a). Before annealing.

Figure IV. 9(b). After 14 hr . anneal at $666^{\circ} \mathrm{C}$.

Figure IV. 9(c). After 2 hr . anneal at $1000^{\circ} \mathrm{C}$.

Figure IV. 9(d). After 60 hr . anneal at $1000^{\circ} \mathrm{C}$.

The standard annealing procedure adopted was:
(a) the crystal was carefully cleaned in hot trichloroethylene, isopropyl alcohol and acetone,
(b) it was then placed in the annealing chamber, and, with the vacuum reduced below $10^{-7}$ Torr, the temperature was raised at a rate of $100^{\circ} \mathrm{C} /$ hour,
(c) the crystal was annealed at $1000^{\circ} \mathrm{C}$ for between 60 and 100 hours, (d) the temperature was reduced from $1000^{\circ} \mathrm{C}$ to $750^{\circ} \mathrm{C}$ at a rate of approximately $10^{\circ} \mathrm{C} /$ hour, then from $750^{\circ} \mathrm{C}$ to room temperature at a rate of approximately $22^{\circ} \mathrm{C} /$ hour.

The crystal was mounted on an aluminium backing plate (see Figure IV.10), when not actually in the annealing or electropolishing systems, to minimise damage during handling.

## IV.2.6 RESULTS OF CRYSTAL PREPARATION

The crystal used to take the X-ray diffraction patterns in Figure IV. 9 was subsequently found to have single crystal electron diffraction spots and had a $X_{\min }$ value of $2.7 \%$ (theoretical value $\sim 2.5 \%$ ) when Rutherford Backscattering dechanneling measurements were made at room temperature.

Figure IV. 11 shows X-ray and electron diffraction patterns of a crystal taken during the standard electropolishing and annealing procedures outlined in this Chapter. Crystals with these diffraction characteristics were selected for channeling/dechanneling measurements. Further selection of best quality crystals was sometimes possible on the basis of observable differences in the dechanneling rates at room temperature and finally at low temperatures of $\sim 41^{\circ} \mathrm{K}$.

## CHAPTER FIVE

## DECHANNELING IN GOLD

#### Abstract

V. 1 THE CHALK RIVER NUCLEAR LABORATORY (C.R.N.L.) CHANNELING FACILITY

Backscattering and channeling measurements were made using the $11^{\circ}$ arm of the 3 MeV Van de Graaff accelerator at C.R.N.L. In this excellent facility, it was possible to change from $1 \mathrm{MeV} \mathrm{H}^{+}$to $2 \mathrm{MeV} \mathrm{He}^{+}$ beams and vice versa within approximately 15 minutes. Two 1 mm diameter apertures placed 2 metres apart in the beam line defined the beam direction, gave a beam divergence of $3.0 \times 10^{-2}$ degrees and a beam size of less than 1.5 mm diameter on the crystal.

The main components of the backscattering chamber are shown in Figure V.1. The two axis goniometer is used to provide Azimuthal and Tilt Rotation of the crystal in order that it can be aligned with the beam (Figure V.2). The silicon detector is positioned at an angle of $150^{\circ}$ to the incident beam direction, in the vertical plane, and subtends an angle with respect to the crystal which is large compared to the critical angle for blocking. The region around the crystal and detector is enclosed by a copper cylinder which collects the beam-induced secondary electron emission from the crystal. This current is added to the current which passed through the crystal to give a measurement of the beam current incident on the crystal. The liquid nitrogen cold finger aids rapid evacuation of the scattering chamber, minimises the contamination of the crystal surface in the backscattering chamber, and cools the silicon detector to its maximum energy resolution

Figure V. 2. GONIONETER AXES

(10-15 keV) temperature. Controlled temperature variation, in the range $40^{\circ} \mathrm{K}$ to $293^{\circ} \mathrm{K}$ range, is provided by a two-stage CRYOMECH cooling system. The lower temperature stage is connected to the copper shield to minimise the condensation of residual gases on the crystal surface. The higher temperature stage is connected to the goniometer head. Thermocouples and heaters accompany both stages.

A block diagram of the backscattered particle detection and energy analysis system is shown in Figure V.3. The system functions as follows: a backscattered particle, of energy $E_{1}$, enters the silicon detector, producing an amplified voltage signal $\mathrm{V}_{1}$, directly proportional to $E_{1}$, at the M.C.A. The M.C.A. then records a count in a channel, the channel number of which is directly proportional to $\mathrm{V}_{\mathrm{l}}$. The pulse generator is used to simulate detector pulses in order to calibrate the channel number scale of the M.C.A. directly in energy. The voltage scale on the pulse generator is first converted to an energy ( MeV ) scale, by calibration with reference to alpha particles of known energy from an americium-241 radioactive source. The ratiometer measures the instantaneous ratio of the number of backscattered particles to the beam current. The ratiometer is used in the initial alignment procedure, since a minimum reading on the ratiometer is obtained whenever a crystal axis or plane is aligned with the beam.

## V. 2 PROCEDURE FOR DECHANNELING MEASUREMENTS

Before the crystal was placed in the backscattering chamber, the alignment of the beam, with respect to the goniometer, was checked. This was done by recording the trace of a "burn" mark produced by the beam impacting on paper fastened to the goniometer head during azimuthal rotation.

Figure V. 3. Block Diagram of Farticle Detecting and Energy Analysis System.

The aluminium backing plate, which held the gold crystal, was then fastened to the goniometer head. The gold crystal had not been touched itself since annealing, all handling was done via this backing plate.

The chamber was evacuated below $10^{-5}$ Torr, the cold finger chilled, and the M.C.A. was calibrated with respect to the pulse generator. A 1 MeV proton beam was used for crystal alignment since proton-induced damage occurs at a greater depth in the crystal than that examined by the $2 \mathrm{MeV} \mathrm{He}{ }^{+}$beam, see Figure V.4. Damage to the crystal is also minimised by stopping the beam when backscattering was not being recorded.

## V.2.1. ALIGNMENT OF 〈110〉 CRYSTAL AXIS WITH THE BEAM

The method used to obtain an approximate alignment of the beam with the required channel axis is described in Appendix $B$. With the channel axis and beam approximately aligned, the goniometer tilt and azimuthal co-ordinates were $\phi^{\prime}$ and $\theta^{\prime}$. The S.C.A. rate, which is the backscattered yield for a given beam fluence, was measured as a function of both $\phi$ and $\theta$ around $\phi^{\prime}$ and $\theta^{\prime}$. The $\langle 110\rangle$ axial dip traced out during these tilt and azimuthal scans is shown in Figures V. 5 and V.6. It can be seen from these scans that the centre of the dip can be determined to approximately $0.1^{\circ}$, which is therefore the limit of the precision of alignment using this method. The final precise alignment was achieved by taking aligned spectra, for a given beam fluence, at different tilt angles slightly offset to the nominal aligned position in order to find the position which gave an aligned spectrum

of minimum dechanneling rate. Thus the final alignment can be made to better than $0.1^{\circ}$, see Figure V.7. Once a crystal was precisely aligned, aligned spectra were recorded using $1 \mathrm{MeV} \mathrm{H}{ }^{+}$and $2 \mathrm{MeV} \mathrm{He}{ }^{+}$beams at room temperature. The dechanneling rates of these spectra were compared from crystal to crystal, see Figure V.8. Any crystal, which had a dechanneling rate significantly higher than the others, was considered to exhibit defect dechanneling and was rejected from low temperature studies.

## V.2.2. SPECTRA RECORDING

A crystal, which did not exhibit defect dechanneling, was then cooled to approximately $40^{\circ} \mathrm{K}$. With the channel axis still aligned to the beam direction, aligned spectra were recorded as a function of increasing temperature using the 2 MeV He + beam. Before each spectrum was recorded, any background leakage current into the Beam Monitor electrometer/integrator was minimised (to less than $1 \%$ of the beam current) by zeroing the electrometer. However, we still found that variations in the spectrum counting rate of up to $5 \%$ occurred, for a given beam fluence. This variation must therefore be considered to give the limit of the precision in calculating the aligned and random fraction values from the measured backscattered spectra.

The random spectrum was taken at room temperature following completion of the set of aligned spectra. The crystal was tilted so that the beam direction did not coincide with a major crystallographic direction and the crystal was azimuthally rotated, to minimise the channeling effect during the recording of the random spectrum.

Figure V. 7. Aligned Spectra for different Tilt Angles, iNeV Protons on Gold.

The total beam fluence on each crystal during the recording of the aligned spectra was approximately $2 \times 10^{15}$ atoms $/ \mathrm{cm}^{2}$ and $2 \times 10^{14}$ atoms $/ \mathrm{cm}^{2}$ for the random spectra.

## V.3. RESULTS OF DECHANNELING MEASUREMENTS

Figure V. 8 shows the room temperature aligned spectra for four crystals, three of which have the same dechanneling rate, within the precision of measurement, and the other (SBG1) exhibiting defect dechanneling. Figures V.9(a) and V.9.(b) show the aligned spectra as a function of temperature for DBG1 and DBG2, respectively, using $2 \mathrm{MeV} \mathrm{He}{ }^{+}$. The random spectra for SBG 7 , DB1 and DBG2 are shown in Figure V.10; in Figure V.11, the aligned spectra of DBG1 and DBG2 at low temperatures are compared. (The M.C.A. recorded data for all spectra of DBG1 and DBG2 are given in Appendix C.) A1though the dechanneling rates at room temperature were the same for DBG1 and DBG2 (Figure V.8), at low temperatures there were significant differences (Figure V.11). Since DBG1 exhibited the lower dechanneling rates, it was taken to represent more closely a defect-free crystal and its spectra were used later in the determination of the measured random fraction versus depth spectra, which were compared with theoretical spectra calculated for defect-free (perfect) gold single crystals. Figures V. 12 and V. 13 show the surface peak yield in the aligned spectra, as a function of temperature, for $D B G 1$ and $D B G 2$, respectively.

Figure V. 13. Surface Peak of Aligned Spectrum of DBG 2 as a function of Temperature, Only $293^{\circ} \mathrm{K}$ and $52^{\circ} \mathrm{K}$ spectra are shown for clarity.

#### Abstract

V. 4 ANALYSIS OF DECHANNELING MEASUREMENTS

The beam energy was required to be constant throughout the measurements. Consequently, the energy (or channel number) of particles backscattered from the crystal surface, $E_{1}$, represented by the centre of the surface peak in the aligned spectra and the centre of the surface edge in random spectra, should be constant throughout the measurements. The channel number of particles backscattered from the crystal surface was found to be coincident, within $\pm 2$ channels ( $\pm 8.5 \mathrm{keV}$ ), for all the $2 \mathrm{MeV} \mathrm{He}{ }^{+}$spectra. The detector resolution was $10-15 \mathrm{keV}$, so the small beam energy variations were considered to be acceptable. The value of $E_{l}$ calculated from $E_{1}=k^{2} E_{0}$, where $E_{0}$ is the nominal beam energy, 2 MeV , and that obtained from the aligned spectrum and the calibration of the M.C.A. differed by $17.0 \pm 4.0 \mathrm{keV}$.

Figures V. 14 and V. 15 show random fraction versus depth spectra as a function of temperature. The energy-to-depth scale conversion and the calculation of random fraction from the aligned and random energy spectra (shown in Figures V.9 and V.10) were made using the methods outlined in Chapter Two. The stopping power data of Ziegler and Andersen ${ }^{28}$ were used.

Table V. 1 shows the surface peak yield, $Y_{S A}$, (normalised to an integrated beam monitor current of $0.1 \mu \mathrm{C}$ ) of the aligned spectra as a function of temperature and the corresponding effective number of surface scattering centres per unit area, $n^{\prime} d x ', ~ c a l c u l a t e d ~ f r o m$

$$
n^{\prime} d x^{\prime}=\frac{Y_{S A}}{Y_{S R}} \cdot \frac{n \Delta E}{2 S_{0}} \quad \text { (see Chapter Two), }
$$

where $Y_{S R}=887 \pm 1 \%$ for $D B G 1$ and $771 \pm 1 \%$ for $D B G 2$,
$\mathrm{n}=5.905 \times 10^{28}$ atoms $/ \mathrm{m}^{3}$,
$\Delta E=4.27 \mathrm{keV} /$ channel and
$S_{0}=115( \pm 5 \%) \times 10^{-15} \mathrm{eV} \cdot \mathrm{cm}^{2} /$ atom from Ziegler and Andersen ${ }^{28}$.
The precisions given for $Y_{S A}$ and $Y_{S R}$ are determined by the statistical
error on their total count values. $Y_{S A}$ is found by extrapolating the aligned yield, through the surface peak to zero at the front edge of the surface peak and integrating the yield above the extrapolated curve, see Figure V. 16.

Now $n^{\prime} d x^{\prime}=n_{d} d x_{d}+n_{S} d x_{S}$, where $n_{S} d x_{s}$ and $n_{d} d x_{d}$ are the contributions from the string atoms and the surface disordered atoms respectively. $n_{d} d x_{d}$ is independent of temperature, while $n_{S} d x_{S}$ is temperature-dependent. As the crystal temperature approaches $0^{\circ} \mathrm{K}, \mathrm{n}_{\mathrm{S}} \mathrm{dx}_{\mathrm{S}}$ decreases to the stringend density, $n d$. Hence an upper limit for $\mathrm{n}_{\mathrm{d}} \mathrm{dx}_{\mathrm{d}}$ is obtained for each crystal by subtracting n d. ( $=1.7 \times 10^{19}$ atoms $\left./ \mathrm{m}^{2}\right)$ from the lowest temperature value of $\mathrm{n}^{\prime} \mathrm{dx}^{\prime}$. This gives $\mathrm{n}_{\mathrm{d}} \mathrm{dx}_{\mathrm{d}}=1.0( \pm 1.8) \times 10^{18}$ atoms $/ \mathrm{m}^{2}$ for DBG1 and $n_{d} d x_{d}=8.8( \pm 2.6) \times 10^{18}$ atoms $/ \mathrm{m}^{2}$ for DBG2. The corresponding temperature dependent values which were calculated for $\mathrm{n}_{\mathrm{S}} \mathrm{dx}_{\mathrm{S}}$ are given in Table V.2.

To determine the measured value of $\chi_{\text {min }}$, the aligned yield was averaged over the range of the surface oscillations (a depth range of approximately $280 \AA$ to $1000 \AA$ ) and divided by the random yield just below the surface. This corresponds to the method used by Barrett ${ }^{39}$.

Figure V. 16. The yield in the shaded triangle is subriracted from the total yield in the surface peak to obtain $Y_{S A}$.

BAGKSCATTERDD ENERGY

TABLE V. 2

| $\mathrm{n}_{\mathrm{S}} \mathrm{dx}_{\mathrm{S}}$ (atoms/m${ }^{2}$ ) | $3.9( \pm 0.6) \times 10^{19}$ | $1.7 \times 10^{19}$ | $2.4( \pm 0.4) \times 10^{19}$ | $3.1( \pm 0.5) \times 10^{19}$ | $4.7( \pm 0.8) \times 10^{19}$ |

The subsurface random yield for DBG1 was $887 \pm 1 \%$ and for DBG was $771 \pm 1 \%$. The mean minimum aligned yields, normalised to an integrated beam monitor current of $0.1 \mu \mathrm{C}$, and the corresponding $\chi_{\text {min }}$ values are tabulated as a function of temperature in Table V.3. The statistical precisions are also shown.

## V. 5 COMPARISON OF EXPERIMENTAL RESULTS WITH THEORETICAL CALCULATIONS

The measured and calculated $\boldsymbol{\chi}_{\text {min }}$ values are compared in Table V.4. The calculated values were obtained using both Lindhard's and Barrett's expressions, which are described in Chapter Two. The $\chi_{3}$ values were calculated using the $n_{d} d x_{d}$ values shown in Section V.4. $\chi_{3}$ was found to be $0.02 \%$ for DBG1 and $0.1 \%$ for DBG2.

The measured $\boldsymbol{X}_{\text {min }}$ and the calculated values for $\boldsymbol{\chi}_{\text {min }}$ (using Barrett's formula) are in excellent agreement for DBG1.

The Random Fraction versus Depth values as a function of temperature were calculated using the SITE approximation (see Chapter Three) and are compared with the spectra obtained for measurements on DBG1 in Figure V.17. The calculated dechanneling rate is approximately $40 \%$ of the experimental. The measured dechanneling rate shows a strong temperature dependence, increasing sixfold from $41^{\circ} \mathrm{K}$ to $293^{\circ} \mathrm{K}$, which implies that there is only a small amount of dechanneling by defects.

## VI. 1 CRYSTAL QUALITY

The first aim in this project was to prepare well-ordered gold single crystals. The x-ray and electron diffraction photographs (see Chapter Four) indicated that the electropolishing and annealing treatment, which we adopted, effectively reduced the defect concentration in the bulk of the crystal and minimised the surface disorder. Table VI.I shows the measured and calculated dechanneling rate as a function of temperature for DBG1 (see Figure V.17). The dechanneling rates were averaged over the depth interval $\sim 2000 \AA$ to $9500 \AA$. The calculated values are obtained using the SITE approximation (Chapter Three) with the critical distance of approach, $r_{c}$, given by $r_{c}{ }^{2}=3 \rho^{2}+0.2 a^{2}$ (Barrett) or $r_{c}^{2}=\rho^{2}+a^{2}$ (Lindhard). The measured dechanneling rate at room temperature is 5.6 times that at $41^{\circ} \mathrm{K}$. This large temperature dependence is in reasonable agreement with that calculated, namely, 5.0 (Lindhard) and 3.6 (Barrett). This strongly indicates that for room temperature, at least, the dechanneling is principally due to multiple scattering from thermally vibrating string atoms and that the contribution from defect scattering is very small, if not completely negligible. This view is supported by the fact that crystals which show small differences in dechanneling rates at low temperatures (Figure V.11), presumably due to residual defects, show agreement at room temperature (Figure V.8).

TABLE VI. 1
Temperature Dechanneling Rates

| Measured (DBG1) | Calculated <br> (Lindhard) | Calculated <br> (Barret) |
| :--- | :--- | :--- |
| $0.107(\% / 1000 \AA)$ | 0.0515 | 0.0579 |
| 0.222 | 0.115 | 0.110 |
| 0.406 | 0.179 | 0.159 |
| 0.599 | 0.259 | 0.210 |

If the number of scattering centres per unit area in the disordered layer, $\mathrm{n}_{\mathrm{d}} \mathrm{dx}_{\mathrm{d}}$, is assumed to be uniformly distributed on the crystal surface, then the value obtained in Section V. 4 for DBG1 (1.0 $\pm 1.8 \times 10^{18}$ atoms $/ \mathrm{m}^{2}$ ) shows that there is significantly less than one monolayer of disorder $\left(1.7 \times 10^{19}\right.$ atoms $\left./ \mathrm{m}^{2}\right)$ on the crystal.

The measured and calculated (Barrett) values of $\chi_{\text {min }}$ for DBG1 are, overall, in excellent agreement (see Table V.4). We note here that the (Lindhard) calculated $\mathcal{X}_{\text {min }}$ values were intended by Lindhard to be only estimates.

The observed strong temperature dependence of the dechanneling rate, the measured surface disorder of less than one monolayer and the agreement of the measured $\chi$ min values with those calculated for perfectly ordered surfaces all lead to the conclusion that the gold crystals are indeed of high quality and exhibit dechanneling characteristic of defect-free crystals.

## VI. 2 EXPERIMENTAL RANDOM FRACTION SPECTRA

In principle the extraction of the Random Fraction versus Depth spectrum from the Aligned and Random (Energy) spectra is quite simple (see Chapter Two). However, several possible complicating factors must be remembered. There is a unique relationship between backscattered energy and depth, via stopping power, in the case of the random spectrum if single Rutherford scattering is assumed. But a channeled particle does not necessarily move through the same average electron density as a particle in the random beam and hence does not necessarily experience the same rate of energy loss. Consequently the depth scales for the random and aligned spectra may be somewhat different ${ }^{10}$. The stopping power for a channeled particle is difficult to characterise and measure. Nevertheless, we have found that the detected energy of particles backscattered from the rear surface of gold single crystal films (~6000 $\AA$ thick) for aligned incidence was only $\sim 7 \%$ higher than that for random incidence. This implies that the channeled and random stopping powers are comparable for shallow depths. Our thin crystals were of rather poor quality as evidenced by high $\chi_{\min }(10-15 \%)$ and dechanneling rate values at room temperature. However, the same observation has been reported by Merkle et al. ${ }^{25}$ using good quality films. Therefore, we feel that the use of the same depth scale for the aligned and random spectra is justified.

In our analysis of the shape of the random spectrum (see Chapter Two), we used Ziegler and Andersen's empirical stopping power data and neglected events arising from more than one large angle scattering. Since the measured and random spectra were in good agreement, the assumption of single Rutherford backscattering being the predominant scattering mechanism and the use of Ziegler and Andersen's stopping power data would appear to be validated.

Thus, we feel that our calculation of the depth scale and the determination of the random fraction from the ratio of the aligned and random spectra is good to within the precision limitation imposed by the beam monitor and the observed thin film tails, namely $5-10 \%$.

## VI. 3 CALCULATED RANDOM FRACTION SPECTRA

The Aarhus group found that calculations made taking into account diffusion in transverse energy and those using the SITE approximation were in agreement at shallow depths (Figure I.2(a)). Nevertheless, they felt that the use of the SITE approximation did not seem reasonable on physical grounds, since diffusion in transverse energy was evident in their calculations ${ }^{15}$.

Both diffusion and SITE approximation calculations are made using the assumption that the initial transverse energy distribution and the critical transverse energy are wel1-defined and known. The theories differ in the calculation of changes in transverse energy distribution with depth.

In our SITE calculations, we assumed that the initial transverse energy distribution was completely described by a potential energy distribution, $\mathrm{p}\left(\mathrm{E}_{\perp_{\mathrm{O}}}\right)$. This is valid if we are comparing with an experimental case where the beam is precisely aligned with the channel axis, the beam divergence is negligible and scattering by the disordered surface atoms is minimal. Precise alignment ( $<0.1^{\circ}$ ) was attained, as described in Chapter Five, and the beam divergence, defined geometrically by the beam line apertures, was approximately $3 \times 10^{-2}$ degrees. Neglecting any spread of the beam due to scattering in the beam line, the corresponding transverse kinetic energy distribution range due to beam misalignment and divergence is $\nmid 10 \mathrm{eV}$, which is
negligible. An expression for the initial transverse kinetic energy distribution, $G\left(E_{\perp_{0}}\right)$, produced by single Rutherford scattering from the disordered surface atoms is given by Björkqvist et al. ${ }^{16}$,

$$
G\left(E_{1_{0}}\right)=n_{d} d x_{d} \cdot \pi \cdot\left(\frac{e^{2}}{4 \pi \epsilon_{0}}\right)^{2} \cdot \frac{Z_{1}^{2} \cdot Z_{2}^{2}}{E_{1_{0}}^{2} E}
$$

$G\left(E_{\perp_{0}}\right)$ is tabulated with $p\left(E_{\perp_{0}}\right)$ in Table VI. 2 for the initial transverse energy range of particles dechanneled within $10,000 \AA . G\left(E_{\perp}\right)$ is calculated using the value of $\mathrm{n}_{\mathrm{d}} \mathrm{dx}_{\mathrm{d}}$ appropriate for DBG1 (1.0 x $10^{18}$ atoms $/ \mathrm{m}^{2}$ ). Table VI. 2 shows that the contribution to the distribution in initial transverse energy caused by scattering in the surface disorder layer, $G\left(E_{\perp_{0}}\right)$, is approximately two orders of magnitude less than $p\left(E_{\boldsymbol{\perp}_{0}}\right)$ and hence can be neglected. Therefore, we feel that the use of $p\left(E_{\perp_{0}}\right)$ for the initial transverse energy distribution is justified in our case.

TABLE VI. 2

$3.29 \times 10^{-7}$
$2.01 \times 10^{-7}$
$1.47 \times 10^{-7}$
$0.82 \times 10^{-7}$

We have used the values suggested by Lindhard ${ }^{14}$ for the critical transverse energy (i.e., $E_{\perp_{c}}=U\left(r_{c}\right)$, where $r_{c}{ }^{2}=\rho{ }^{2}+a^{2}$ ) and for the potential screening parameter, $C(C=\sqrt{3})$. Lindhard notes that these values are to be regarded as estimates. We have therefore investigated the effect on the calculated Random Fraction spectra of variations in
the values of $C$ and $E_{\perp_{C}}$ (see Figures VI.1 and VI.2, respectively). In the case of $\mathrm{E}_{\perp_{C}}$, we altered the magnitude of $\mathrm{E}_{\perp_{C}}$ but left its temperature dependence unchanged (i.e., $E_{\perp_{c}}=\alpha \cdot U\left(r_{c}\right)$, where $0.1 \leq \alpha \leq 2.0$ ). In another attempt we used $r_{c}{ }^{2}=3 p^{2}+0.2 \mathrm{a}^{2}$, which gives agreement at the surface and is consistent with the results of Barrett's Monte Carlo $\mathcal{X}_{\text {min }}$ calculations. However, the calculated dechanneling rate appears to be relatively insensitive to the value of these parameters, $C$ and $E_{\perp}$ c (Figures VI.1 and VI.2). Therefore, we conclude that there is a real difference between the measured dechanneling rate and that calculated using the SITE approximation.

For Random Fraction values up to $10 \%$, the values calculated using the SITE approximation by the Aarhus group ${ }^{15}$ for 1.6 MeV protons on $\langle 110\rangle$ silicon and 2.0 MeV protons on $\langle 100\rangle$ tungsten and those reported by Foti et al. ${ }^{18}$ for 1.5 MeV protons on 〈111〉 silicon showed similar disagreement from the measured values to those we observed for $2 \mathrm{MeV} \mathrm{He}{ }^{+}$in $\langle 110\rangle$ gold.

In the SITE approximation, statistical equilibrium is assumed ${ }^{14}$, i.e., particles of the same transverse energy uniformly populate their accessible area in transverse space. Barrett ${ }^{40}$, using Monte Carlo calculations to study the causes of the sub-surface peaks in the aligned spectra, has shown that channeled particles experience a focussing effect on entering the crystal surface. He suggests that this focussing effect constitutes a breakdown in statistical equilibrium and affects the yield even beyond the near-surface region. Therefore, a basic assumption (statistical equilibrium) may not be completely valid in the surface region ( $<1$ micron) and this may be a contributing cause to the observed difference between measured and calculated dechanneling rate.

(c) $E_{L_{c}}=U\left(r_{c}\right)$, (d) $E_{1_{c}}=2 U\left(r_{c}\right)$ 。

## VI. 4 CONCLUSION

The electropolishing and annealing treatments used in this project were effective in preparing high quality defect-free gold single crystals.

The measured Random Fraction spectra have been shown to represent dechanneling of $2 \mathrm{MeV} \mathrm{He}^{+}$in well-ordered <110〉 gold.

The calculated dechanneling rates based on the SITE approximation are $40-50 \%$ of those measured, although they show approximately the same temperature dependence. The differences are not considered to be due to the use of incorrect values for the theoretical parameters but may be due to lack of statistical equilibrium in the transverse motion in the surface region.

## APPENDIX A

THE CONTINUUM POTENTIAL, $\mathrm{U}(\mathrm{r})$
$V\left(P_{n}\right)$ is the interatomic potential between particle $P$ and any string atom, $n$ (see Figure A.1).
$\sum_{\mathrm{n}} \mathrm{V}_{\mathrm{n}}\left(P_{\mathrm{n}}\right)$ is the total potential experienced by P and is periodic along $z$. By definition $U(r)$ is the average of $\sum_{n} V\left(\rho_{n}\right)$ along $z$. Since $\sum_{\mathrm{n}} \mathrm{V}\left(\rho_{\mathrm{n}}\right)$ is periodic, then $\mathrm{U}(\mathrm{r})$ is the average of $\sum_{\mathrm{n}} \mathrm{V}\left(\rho_{\mathrm{n}}\right)$ between $\left.\mathrm{z}= \pm \mathrm{d} / 2\right)$. Now the contribution of the string atom $n$ to $U(r)$ as $P$ is moved between $z= \pm d / 2$ is given by:

$$
U_{n}=1 / d \int_{-d / 2}^{+d / 2} V\left(P_{n}\right) \cdot d z
$$

where

$$
\rho_{n}^{2}=(n d-z)^{2}+r^{2}
$$

By changing the variable from $z$ to $z^{\prime}$, where $z^{\prime}=n d-z$, we may write:

$$
U_{n}=1 / d \int_{d(n+1 / 2)}^{d(n-1 / 2)} V\left(\rho^{\prime}\right) \cdot d z^{\prime}
$$

where $\rho^{\prime 2}=z^{\prime 2}+r^{2}$.

$$
\text { Therefore, } \begin{aligned}
U(r) & =\sum_{n} U_{n} \\
& =1 / d \int_{-\infty}^{+\infty} V(\rho) \cdot d z .
\end{aligned}
$$

## Figure A. 1.

## APPENDIX B

THE APPROXIMATE ALIGNMENT OF A CHANNEL AXIS WITH THE BEAM DIRECTION

By indexing the spots in the spots in the Laue x-ray diffraction pattern, we had ascertained the approximate ang1e, $\phi_{a}^{\circ}$, that the $\langle 110\rangle$ direction in a crystal made with the normal to the crystal surface. With the crystal fastened to the goniometer head and the goniometer setting at $\left(0^{\circ}, 0^{\circ}\right)$, then the azimuthal axis is coincident with the beam direction, see Figure B.1. The crystal is then tilted through an angle $\phi^{\circ}$, where $\phi^{\circ}>\phi_{a}^{\circ}$, and rotated around the azimuthal axis (Figure B.2). During the azimuthal rotation the beam passes through a set of directions in the crystal, lying on the perimeter of the base of the cone traced out during rotation (Figure B.3). A direction in the crystal can therefore be identified with the azimuthal and tilt coordinates, $\left(\phi^{\circ}, \theta^{\circ}\right)$, of its projection on to the base of the cone. The Ratiometer reading is monitored during the azimuthal rotation and the dips in the reading recorded as a function of the azimuthal angle, $\theta^{\circ}$ (see Figure B.4). A dip occurs whenever the beam direction is incident along a plane containing the $\langle 110\rangle$ direction. Since the intersection of planes containing the <110> direction is the <110> axis itself, then the intersection of the projected planes will give the coordinates $\left(\phi^{\prime \circ}, \theta^{\prime \circ}\right)$ of the projected $\langle 110\rangle$ direction (see Figure B.5). By rotating the goniometer to $\left(\phi^{\prime \circ}, \theta^{\prime \circ}\right)$, the beam direction is now coincident with the 〈110〉 direction. This alignment is approximate, since the azimuthal dip is often quite wide (see Figure V.6).

Fizure B. 5.
The ratiometer dips are used to locate the projections of the crystallorraphic planes containing the <110>direction, Their intersection gives the coordinates ( $\phi^{\prime}, \theta^{\prime}$ ) of the projection of the $\langle 110\rangle$ axis.

APPENDIX C

## M. C. A. DATA

The following pages give the raw M. C. A. data in the aligned and random (energy) spectra for crystals DBG1 and DBG2. The heading gives the crystal name, type of spectrum, crystal temperature and integrated beam current, respectively.

The data is collected in the form: counts per channel versus channel number. The first column (from the left hand side) gives the channel numbers of the yields in the second column. The channel numbers increase from left to right across the remaining rows of yields.

The channel number scale can be converted to a backscattered energy scale, using the $M$. C. A. calibration:
$E_{1}(\mathrm{keV})=4.27 \mathrm{x}$ channe1 number +40.60

In the discussion of the calculations using the SITE approximation, we considered certain parameters ( $E_{\mathcal{L}_{c}}$ and $C$ ) used in the calculation and also the applicability of using $p\left(E_{\perp_{0}}\right)$ to describe the initial transverse energy distribution. However, we did not discuss the derivation of the expressions used in the calculation of $\left\langle\mathrm{dE}_{\perp} / \mathrm{dz}\right\rangle$, which were approximated by Lindhard ${ }^{14}$ and Foti et al. ${ }^{18}$

The dominant term in $\left\langle\mathrm{dE}_{\perp} / \mathrm{dz}\right\rangle$ is $\left\langle\left(\mathrm{dE}_{\perp} / \mathrm{dz}\right)_{\mathrm{n}}\right\rangle$ for high transverse energies, as can be seen in Figures I.1(a) and III.I.
$\left\langle\left(\mathrm{dE}_{\perp} / \mathrm{dz}\right)_{n}\right\rangle$ is given by $\frac{\mathrm{d}}{4 \mathrm{E}}\left\langle\delta \overrightarrow{\mathrm{K}}(\mathrm{r})^{2}\right\rangle$ and Lindhard gives

$$
\left\langle\delta \overrightarrow{\mathrm{K}}(\mathrm{r})^{2}\right\rangle=\frac{\rho^{2}}{2}\left\langle\frac{\mathrm{~K}^{2}(\mathrm{r})}{\mathrm{r}^{2}}+\mathrm{K}^{\prime}(\mathrm{r})^{2}\right\rangle \text {, see Equation (III.8). }
$$

This was derived by summing the squares of the momentum transfers (corresponding to the $\delta \overrightarrow{\mathrm{K}}$ values) along the path of the particle and expanding to the lowest contributing order in $s / r$, where $\vec{s}$ is the distance of a thermally-displaced atom from its static position.

The Aarhus group ${ }^{23}$ has extended the calculation to include the next contributing order of the force fluctuation, with the averaging again taken over the distribution in the thermally displaced string atoms, $P(\vec{s})$, and over the positions $\vec{r}$ in the area accessible to particles of transverse energy $\mathrm{E}_{\perp}$.

When these first two contributing terms are added to give a new value for $\left\langle\left(\mathrm{dE}_{\perp} / \mathrm{dz}\right)_{\mathrm{n}}\right\rangle$, and this is used to modify the calculated Random

Fraction versus depth spectrum, then the calculated and measured Random Fraction versus depth spectra are found to be in good agreement, see Figure AD.1.

Hence the gold single crystals, which we have prepared, show all the dechanneling characteristics of well-ordered defect-free gold as expected from theory.
