#### Abstract

The crystal structure of $\mathrm{Cu}(\mathrm{PM})_{2}\left(\mathrm{NO}_{3}\right)_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ (where PM is pyridoxamine, $\mathrm{C}_{8} \mathrm{H}_{12} \mathrm{~N}_{2} \mathrm{O}_{2}$ ) has been determined from three dimensional x-ray diffraction data. The crystals are triclinic, space group $p \overline{1}, a=14.248$ (2), $b=8.568$ (1), $c=9.319(1) \AA, \alpha=94.08(1), \beta=89.73(1), \gamma=99.18(1)^{\circ}, z=2$, $\mu\left(\operatorname{MoK}_{\alpha}\right)=10.90 \mathrm{~cm}^{-1}, \rho_{0}=1.61 \mathrm{~g} / \mathrm{cm}^{3}$ and $\rho_{\mathrm{c}}=1.61 \mathrm{~g} / \mathrm{cm}^{3}$. The structure was solved by Patterson techniques from data collected on a Picker 4-circle diffractometer to $2 \theta_{\max }=45^{\circ}$. A11 atoms, including hydrogens, have been located. Anisotropic thermal parameters have been refined for all nonhydrogen atoms. For the 2390 independent reflections with $\mathrm{F} \geq 3 \sigma(\mathrm{~F})$, $R=0.0408$.

The results presented here provide the first detailed structural information of a metal complex with PM itself. The copper atoms are located on centres of symmetry and each is chelated by two PM zwitterions through the amino groups and phenolate oxygen atoms. The zwitterionic form found in this structure involves the loss of a proton from the phenolate group and protonation of the pyridine ring nitrogen atoms. The two independent $\mathrm{Cu}(\mathrm{PM})_{2}$ moieties are symmetrically bridged by a single oxygen atom from one of the nitrate groups. The second nitrate group is not coordinated to the copper atoms but is central to an extensive hydrogen bonding network involving the water molecule and uncoordinated functional groups of PM.

## Acknowledgements

The author would like to express his deepest appreciation to Professor M. F. Richardson for her helpful supervision, encouragement and patience during the course of this work.

In addition, thanks should go to Dr. J. M. Miller, Chairman of the Department of Chemistry, the other members of the Department and Dr. D. M. Thompson of Wofford College, South Carolina for their valuable suggestions and assistance. The writer is also grateful to Dr. G. M. Sheldrick for providing the SHELX system of computing programmes which facilitated solution and refinement of this structure and to Mrs. J. Glazebrook and Mr. W. Bell for their assistance in adapting SHELX to the computer systems at Brock University. Special thanks are due Mrs. T. Franklin for providing the crystals.

Financial support for this research was obtained from the National Research Council of Canada and the Ontario Graduate Scholarship Programme.

## Chapter I

## Introduction

The class of compounds that we call vitamins was discovered through the realization that certain diseases could be prevented or cured by changes in the diet. That such relationships existed has been known for hundreds of years. For example, the therapeutic value of animal liver towards night blindness was recognized by ancient Greek, Roman and Arab physicians (1). History also records that citrus fruits were used by sailors to prevent scurvy during their long voyages at sea. However, it is only within the past century that substances not classified as fats, carbohydrates, proteins or minerals were found to be essential for life.

The term, vitamine (L. vita + amine), was applied to these unknown compounds by Funk (1) in 1912 who believed these dietary factors to be nitrogenous. This word was later shortened to vitamin when it was discovered that not all these essential factors contained nitrogen.

Vitamin B was originally termed the "anti-beriberi factor" as a result of investigations by Eijkman (2) who produced polyneuritis (beriberi) in fowl fed polished rice and effected a cure by adding rice bran to their diet. As a result of further study and improved techniques, it was found that vitamin $B$ was not a single compound but a mixture of vitamins. In 1934, György (3) added concentrates of thiamine ( $B_{1}$ ) and riboflavine ( $B_{2}$ ), known components of the vitamin $B$ complex, to a vitamin $B$ deficient ration being fed to rats. He found that poor growth and a type of dermatitis called acrodynia resulted from this diet and that these symptoms could be prevented by feeding other sources of the vitamin B complex. György
termed this unknown component vitamin $\mathrm{B}_{6}$ (3).
In 1938, several research groups (4-6) reported the isolation of crystalline vitamin $B_{6}$. The processes of degradation and synthesis by which this compound was characterized as pyridoxol (see figure 1) have been described by Wagner and Folkers (7). Later investigations by Sne11 (3) revealed that a number of related compounds also produced vitamin $\mathrm{B}_{6}$ activity and today there are several compounds known collectively as pyridoxine or vitamin $\mathrm{B}_{6}$ (see Figure 1).

This hectic research activity continued into the 1940's when it became evident that vitamins played important roles in several enzymatic reactions. Enzymes, which act as biological catalysts, are composed of an apoenzyme or protein portion and a cofactor portion. The latter may be an inorganic divalent ion (activator) such as $\mathrm{Ca}(\mathrm{II}), \mathrm{Mg}(\mathrm{II})$ or Zn (II) or an organic molecule (coenzyme) such as a vitamin derivative.

The coenzyme form of vitamin $\mathrm{B}_{6}$ is pyridoxal phosphate (PLP) or codecarboxylase. In this form, vitamin $B_{6}$ is involved in a variety of the enzymatic transformations and metabolic reactions of amino acids. These reactions include transamination, decarboxylation, condensation, substitution and racemization reactions which serve to modify the structural skeletons of amino acids (8). Enzymes incorporating PLP also contribute to the biosynthesis and metabolism of sulphur-containing amino acids, tryptophan, nicotinic acid, riboflavine and folic acid (8).

The sequence of these enzymatic reactions is shown schematically in Figure 2. The first step involves binding of PLP to the apoenzyme and a Schiff base condensation of PLP and the $\varepsilon$ amino group of a lysine residue to form the holoenzyme (I). Biochemical studies involving resolution and

FIGURE 2. SCHEMATIC DIAGRAM OF ENZYMATIC REACTIONS INVOLVING VITAMIN B ${ }_{6}$

TRANSIMINIZATION

reactivation of holoenzymes suggest that a rapid association is followed by a much slower conformational change (9). The latter is probably due to interactions between various protein sites and substituents on the pyridine ring. In fact, it has been shown that each functional group contributes to the binding of the coenzyme (10). The imine bond itself is not of primary importance in bonding since it is broken in the next step and since certain apoenzymes can be fully activated by PMP (11).

The holoenzyme then reacts with the incoming $\alpha$-amino acid which displaces the lysyl residue to form a second Schiff base (II). The formation of this complex labilizes the bonds to the $\alpha$-carbon labelled $a, b$ and $c$. The weakening of these bonds is effected by the imine double bond which is in conjugation with a protonated pyridine ring. Many of the reactions involving PLP-dependent enzymes can be classified in terms of which of these bonds is actually broken (11).

The formation of a complex such as II appears to be common to most enzymes incorporating PLP. The fact that a given enzyme catalyzes only one reaction type can be explained by considering the conformation of the groups attached to the $\alpha$-carbon (12). As the sigma bond is broken, the electron density in the delocalized $\pi$ system of the Schiff base is increased. In order to lower the energy of the transition state, the bond to the leaving group should be perpendicular to the plane of the Schiff base. The orientation required for a particular reaction is determined by the structure of the binding sites in different enzymes (12). The stereochemical aspects of PLP catalysis have been reviewed by Dunathan (13).

After bond cleavage, the ketimine form of the Schiff base undergoes hydrolysis to form product and enzyme bound PMP. The latter may undergo a reverse reaction with an $\alpha$-keto acid to regenerate PLP.

From the above discussion, it can be seen that the catalytic effect of enzymes is due to several features (14). By selectively binding PLP, and probably the amino acid as well, the enzyme serves to increase the local concentration of reactants. The various side chains present at the active site can produce solvent effects resulting in an increase or decrease in the strength of an acid. Such effects can also lower the redox potential difference between reactants and products. The enzyme may also participate in the general acid catalysis of the condensation reaction between PLP and the lysine residue. The resulting formation of an imine bond facilitates addition of the amino acid. The effect of the enzyme on stabilization of the transition state has already been mentioned. However, the planarity of the complex itself may also be influenced by the enzyme. Finally, the enzyme may act directly to provide the excitation energy for the reaction (14).

Much of the current understanding of these enzymatic processes has been derived from the study of model reactions where metal ions replace the enzyme (15). Perhaps the most successful model system is the transamination reaction shown schematically in Figure 3. An $\alpha$-amino acid, $P L$ and a metal ion react to form an aldimine Schiff base complex which passes through a resonance stabilized intermediate to form a ketimine complex. The latter then dissociates to give $P M$, metal ion $p l u s$ the $\alpha$-keto acid. Longenecker and Snell (16) have suggested that the metal ion in this and other model reactions could serve one or more of the following catalytic functions:
(a) act as a template to assist the formation of the Schiff base,
(b) stabilize the Schiff base and thus promote its formation,
(c) maintain planarity of the conjugated double bonds to facilitate electron transfer,
(d) reinforce the withdrawal of electrons from the $\alpha$-carbon.

FIGURE 3.
THE TRANSAMINATION REACTION

ALD IMINE SChiff base complex

KETIMINE SChIFF BASE COMPLEX

With respect to the first of these, a number of workers (17-19) have found experimental evidence that metal ions trap preformed Schiff base rather than providing a kinetic template for its formation. Metalindependent paths for Schiff base formation have been found for $\mathrm{Cu}, \mathrm{Ni}$ and Co while both metal-independent and metal-dependent paths exist for $\mathrm{Mg}, \mathrm{Mn}$, $\mathrm{Zn}, \mathrm{Cd}$ and $\mathrm{Pb}(20,21)$.

Hopgood and Leussing (21) found that for divalent metal ions, the order of catalytic efficiency was $\mathrm{Pb} \gg \mathrm{Cd}>\mathrm{Mn} \sim \mathrm{Mg}>\mathrm{Zn} \gg \mathrm{Co}, \mathrm{Ni}, \mathrm{Cu}$ (very sma11). It was noted that the metal ions most effective as catalysts are those with no partly filled d orbitals. Complexes of these ions with ammonia tend to be more labile than those of the catalytically inactive Co, Ni and Cu . At the same time, such complexes do not necessarily conform to particular geometries, which in ions with incompleted subshells are stabilized by ligand field effects. Since a fixed spatial orientation of the reactants to the metal ion causes inactivity, Hopgood and Leussing (21) suggest that the term promnastic (Gr. matchmaker) rather than template be used to describe the effect of a catalytic agent which forms a ternary complex with two reactants but which imposes a minimum steric requirement on them. These authors (21) also point out that Schiff bases are unstable in acidic solution and that metal ions, whether kinetically active or not, are necessary for the formation of observable amounts at equilibrium. Thus, although the model mechanisms are not fully understood, it would appear that at least some metal ions do assist Schiff base formation in a manner similar to that found in enzymes (22).

The reaction specificity of enzymatic systems is difficult to achieve in model systems although a few examples exist. Thanassi (23) has shown
that substitution at the $\alpha$-carbon of $\alpha$-aminomalonates can affect reaction pathways in the 5-deoxypyridoxal catalyzed reactions of these compounds. The electronegativity of the leaving group has been found to be critical in determining whether $\beta$-elimination predominates over other vitamin $B_{6}$ catalyzed reactions (24). Tenenbaum, Withrup and Abbot (25) have demonstrated selective deuteration at the $\alpha$ and $\beta$ positions of amino acids. The selectivity of this reaction, which is catalyzed by $\mathrm{Al}^{3+}$ and PL was attributed to the pH dependence of the reactivity of the dihydropyridine intermediate. Finally, Blum and Thanassi (26) have found that the choice and concentration of metal ion can result in reaction specificity. They suggest (26) that the metal ion is able to impose the steric control necessary to promote the mechanism of reaction specificity proposed by Dunathan (13) (vide supra).

X-ray crystallography has been used to investigate the stereochemistry of Schiff base complexes. Solid compounds were first isolated by Christensen (27) who found a $2: 1$ ligand to metal ratio for $\mathrm{Mn}(\mathrm{II})$, $\mathrm{Ni}(\mathrm{II}), \mathrm{Zn}(I I)$, Fe(II) and $F e(I I I)$ but a $1: 1$ ratio in the case of $\mathrm{Cu}(I I)$. The crystal structures of two copper complexes $(28,29)$ revealed that the amino acid and vitamin moieties are approximately coplanar, occupying three sites in the square pyramidal geometry. This supports the suggestion (16) that the metal ion serves to maintain the planarity of the conjugated system and thus facilitate electron transfer. In contrast, the metal ions $\mathrm{Mn}(\mathrm{II})$, $\mathrm{Ni}(I I)$ and $\mathrm{Zn}(I I)$ form $2: 1$ complexes in which the metal is octahedrally coordinated and the Schiff base is non-planar (30,31).

These results are particularly interesting in view of the fact that $\mathrm{Cu}(I I)$ has a very small catalytic effect on Schiff base formation but is
relatively very active in promoting the non-enzymatic transamination reaction. It would seem that both these effects can be attributed to the steric requirements of the unfilled d orbitals in $\mathrm{Cu}(I I)$. That is, these requirements do not permit the promnastic mechanism proposed (21) for the former reaction but do fulfill the necessity of steric rigidity in the transition state of the latter.

The extension of this hypothesis to other metals is dependent on the results of further experimentation, especially additional structure determinations. It is known that the comparative activities of metal ions in model transamination reactions follow the order (31): $\mathrm{Ga}(\mathrm{III})>\mathrm{Cu}(\mathrm{II})$ > Al(III) > Fe(II) > Fe(III) z Zn(II) > In(III) z Ni(II) > Cd(II) > Sc(III). The interpretation of this catalytic order is still being formulated (32) although as early as 1957, Longenecker and Snell (16) realized that the order of metal ion activities closely parallels the stabilities of chelates for these metals with $P M$ and other ligands. This observation plus the suggestion (33) that PM chelates of metals have a role in the dissociation of the ketimine Schiff base (see Figure 3) has resulted in a number of studies involving PM and metal ions alone.

In $P M$, there are several potential binding sites: the heterocyclic nitrogen, the phenolic oxygen, the hydroxymethyl oxygen and the aminomethyl nitrogen. Chelation of metal ions by the phenolic and amino groups to form a stable six-membered ring can also occur. The type of complexation which takes place is dependent on which form of PM dominates (see Figure 4). It is thought that PM normally exists in solution as zwitterion II (34) which would be incapable of chelation due to protonation of the amino group. Thus, if a chelate complex exists as proposed (33) for model transamination

FIGURE 4. FORMS OF PYRIDOXAMINE

reactions, form II must be converted to the non-polar form $I$ or to the new zwitterion III.

Williams and Neilands (35) studied the interaction of PM with metal ions by titrating from acidic to basic solution in the presence of $\mathrm{Cu}(I I)$, $\mathrm{Fe}(\mathrm{II}), \mathrm{Fe}(\mathrm{III}), \mathrm{Al}(\mathrm{III})$ and $\mathrm{Mg}(I I)$. It was shown that the only metal ion effectively chelated by $P M$ was $C u(I I)$. The formula of the complex was determined spectrophotometrically to be $\mathrm{Cu}(\mathrm{PM})_{2}$ (35). The high affinity of PM for $\mathrm{Cu}(I I)$ was also observed by other authors (36,37). Matsushima and Martell (38) obtained clear, stable absorption spectra for PM complexes containing $\mathrm{Zn}(I I), \mathrm{Cu}(I I)$ and $\mathrm{Ni}(I I)$ in methanol. The instability of $\mathrm{Mn}(I I)$ and $C o(I I)$ complexes was attributed to oxidation-reduction reactions involving the metal ion. Results of a recent study using polarographic methods indicate that monodentate coordination through the heterocyclic nitrogen may be present in a $\mathrm{Zn}(\mathrm{II})$ complex although chelate formation was found for the corresponding $C d(I I)$ complex $(39,40)$.

Chelation of metal ions by PM has been postulated by many of the above authors whose results compare favourably with studies of Schiff base complexes. However, in contrast to the latter where structure determinations have been completed, little is known about the structure of the PM molecule (particularly with respect to protonation of the heterocyclic nitrogen atom) in metal-PM complexes. The following results provide the first detailed structural information of a metal complex with PM itself.

## Chapter II

## Experimental

## A. Crystal Selection and Density Determination

Dark green crystals of $\mathrm{Cu}(\mathrm{PM})_{2}\left(\mathrm{NO}_{3}\right)_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ were obtained by Mrs. T. Franklin from the evaporation of an equimolar solution of pyridoxamine (PM) and copper (II) nitrate in water. Plate-shaped crystals suitable for further study by x-ray diffraction were chosen with the aid of a polarizing microscope. The selection was based on clarity, size, regularity of shape and the sharpness of the extinctions when the crystal was rotated in plane polarized light.

Several crystals were mounted on thin glass fibres with Lepage's Five Minute Epoxy cement. One of these was used by Mrs. T. Franklin for preliminary photographic studies. However, the doubling of spots on upper layer Weissenberg photographs indicated that the crystal was actually twinned. A second crystal, with the dimensions $0.43 \times 0.15 \times 0.03 \mathrm{~mm}$, was found to be suitable for the complete $x$-ray structure determination.

Following the selection of suitable crystals, the density of $\mathrm{Cu}(\mathrm{PM})_{2}\left(\mathrm{NO}_{3}\right)_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ was determined by Mrs. T. Franklin to be $1.61 \mathrm{~g} \mathrm{~cm}{ }^{-3}$. The flotation technique used in this determination is fully described elsewhere (41).

## B. Photographic Studies

Oscillation photographs were taken on a Picker x-ray diffraction instrument using a Weissenberg camera from Charles Supper Co. and No-Screen Medical X-ray Film from Kodak. Fifteen minute exposures to
$\mathrm{CuK}_{\alpha}$ radiation were used for all photographs. The oscillation range of the crystal was $15^{\circ}$. The films were processed using Rapid X-ray Developer and X-ray Fixer from Kodak. Alignment of the crystal was accomplished by the methods outlined in Stout and Jensen (42).

Once the crystal was aligned, the above apparatus was used to take equi-inclination Weissenberg photographs. Nickel filtered $\mathrm{CuK}_{\alpha}$ radiation $(\lambda=1.5481 \AA)$ and exposure times of eleven to sixteen hours were used for all photographs. The h0l, h1l, h2l and h3l layers were photographed using camera settings based on the lattice dimensions obtained from the oscillation photographs (43).

The crystal was transferred to a precession camera (Charles Supper Co.) and aligned (44) using unfiltered $\mathrm{CuK}_{\alpha}$ radiation. Photographs of the Okl, $1 k \ell, 2 k \ell, h k 0$ and $h k l$ layers were then taken using a nickel filter and exposure times of eight to twelve hours. Calculations of camera settings for non-zero layers followed Buerger (45).

The lack of symmetry, of systematic absences and of orthogonal axes indicated that the crystal was triclinic. Axes were chosen such that the reciprocal unit cell angles $\alpha^{*}, \beta^{*}$ and $\gamma^{*}$ were all less than $90^{\circ}$. The photographs were indexed on this basis and it was found that reflections having odd values of $k$ were systematically weak. This observation was attributed to a "pseudo" translational symmetry element along the $y$ axis.

## C. Diffractometer Studies

The crystal was transferred to a Picker Four-Circle Diffractometer. The methods of crystal alignment given in Stout and Jensen (46) were employed. Zirconium filtered $\mathrm{MoK}_{\alpha}$ radiation $(\lambda=0.7107 \AA$ ) was used for all diffractometer studies.

Accurate reciprocal unit cell dimensions were obtained from $2 \theta$ values measured on the diffractometer. Peak profiles were obtained by taking ten second counts at small increments ( 0.02 to $0.05^{\circ}$ ) of $2 \theta$. The centre of the reflection was found by averaging the half-height values. This procedure was then repeated for the reflection at $-2 \theta$ and the results were averaged to give a value used in the calculations. Several measurements were used in the determination of each parameter.

The accuracy of the results was further enhanced by the sharp definition of the reflections where permitted by resolution of the $\operatorname{MoK}_{\alpha_{1}}(\lambda=0.70926 \AA)$ and $\operatorname{MoK}_{\alpha_{2}}(\lambda=0.71354 \AA)$ doublet. Whenever possible, both values were used in the calculations. Both the reciprocal cell lengths, $a^{*}, b^{*}$ and $c^{*}$, and the corresponding angles, $\alpha^{*}, \beta^{*}$ and $\gamma^{*}$ were calculated by equation (1) (47).

$$
\begin{gathered}
\frac{\sin \theta}{\lambda}=\frac{1}{2}\left[h^{2} a^{*} 2+k^{2} b^{*} 2+\ell^{2} c^{*} 2\right. \\
+2 h k a^{*} b^{*} \cos \gamma^{*}+2 h l a^{*} c^{*} \cos \beta^{*} \\
\left.+2 k \ell b^{*} c^{*} \cos \alpha^{*}\right]^{\frac{1}{2}}
\end{gathered}
$$

A summary of these results is presented in Table 1. The direct cell constants were found (48) to be $a=14.248$ (2), $b=8.568$ (1), $c=9.319$ (1) $\AA$, $\alpha=94.08(1), \beta=89.73(1)$ and $\gamma=99.13(1)^{\circ}$ where the estimated standard deviation in the last figure is given in parentheses. Assuming 2 molecules per unit cell, the calculated density is $1.61 \mathrm{~g} \mathrm{~cm}^{-3}$.

Data collection took place in two stages, first of all to a maximum $2 \theta$ of $35^{\circ}$ which permitted solution of the structure and later to $45^{\circ}$ to allow location of hydrogen atoms and final refinement. All the data were collected from the same crystal using the $\omega-2 \theta$ scan technique, with $\omega$ changing to one half the rate of $2 \theta$. The scan rate was $1^{\circ}$ per minute over a $1.3^{\circ}$ range centred on calculated peak positions. For very intense reflections, the peak counting rate was reduced to below $40,000 \mathrm{cps}$ by inserting 0.013 mm

zirconium filters in the reflected beam. Background intensities were counted for ten seconds at each end of the scan.

The intensity of a standard reflection, $(-5,2,1)$ was measured at one hour intervals in order to monitor instrumental fluctuation and possible crystal decomposition. Although more than a year separated the two sets of data collection, there was no significant drop in the intensity of the standard indicating the overall stability of the crystal. Minor fluctuations were attributable to instrumental instability resulting from variations in humidity and temperature.
D. Data Reduction

The net intensity of a reflection was computed by equation (2):
$N_{p}=N_{T}-4\left(N_{B_{1}}+N_{B_{2}}\right)$
where $N_{p}, N_{T}, N_{B_{1}}$ and $N_{B_{2}}$ are the net, the total and two background counts respectively. The data between successive measurements of the standard were corrected according to the number of intervening reflections. A11 data were normalized to the initial intensity of the standard reflection. In cases where extra filters had been used, the measured intensity was multiplied by a factor of the form $10^{\mathrm{ax}}$ where x is the number of filters and a $(=0.0549)$ was an empirical constant.

Lorentz and polarizing corrections were applied to convert the net intensities, $I$, into structure factors by equation (3):

$$
\begin{equation*}
F(h k \ell)=\left(\frac{I(h k \ell)}{L p}\right)^{\frac{1}{2}} \tag{3}
\end{equation*}
$$

The combined form of the Lorentz and polarizing factors, Lp, is given by equation (4) for 4 -circle diffractometer data:

$$
\begin{equation*}
\mathrm{Lp}=\frac{1+\cos ^{2} 2 \theta}{\sin 2 \theta} \tag{4}
\end{equation*}
$$

where $\theta$ is the Bragg angle of the hkl reflection. No corrections were made for extinction or absorption $\left(\mu\left(\operatorname{MoK}_{\alpha}\right)=10.90 \mathrm{~cm}^{-1}\right)$.

Initially, for the data to $35^{\circ}$, standard deviations were calculated by the procedure detailed in Stout and Jensen (49):

$$
\begin{equation*}
\sigma(F)=(L p)^{-\frac{1}{2}} \frac{N_{T}+r^{2} N_{B}+\left(k N_{p}\right)^{2}}{N_{T}-N_{B}} \tag{5}
\end{equation*}
$$

where $r(=4)$ is the ratio of the scan time to the total time required to take two background counts and $k$, a constant, was set to 0.05 . The value of $1 / \sigma^{2}(F)$ is often used as a weight factor for the reflection data. In the latter stages of the structure refinement, it became possible to refine the weighting scheme (vide infra) and for calculations using the complete data set, $k$ was set to 0.00 . The value of $F$ was set to 0.01 and $\sigma(F)$ to 1000 for reflections with no net intensity.

A total of 2931 reflections were measured having $2 \theta \leq 45^{\circ}$. Of these, 2390 had $\mathrm{F} \geq 3 \sigma(\mathrm{~F})$ and were classified as observable. The remaining 541 unobserved reflections were assigned zero weights during the refinement procedures and were not included in the R-factor calculations. In the programme SHELX (55), which was used for the actual refinement of the structure, the scattering factors were calculated from the analytical expression (5):

$$
\begin{equation*}
f\left(\lambda^{-1} \sin \theta\right)=\sum_{i=1}^{4} a_{i} \exp \left(-b_{i} \lambda^{-2} \sin ^{2} \theta\right)+c \tag{6}
\end{equation*}
$$

The coefficients $a_{i}, b_{i}$ and $c$ for $C u, C, H, N$ and 0 as well as the real and imaginary parts of the corrections for anomalous dispersion were taken from the International Tables for X-ray Crystallography (50).

## Chapter III

Structure Determination and Refinement

## A. The Heavy Atom Method

Using the initial data set to $35 \%$, a three-dimensional unsharpened Patterson function was calculated by:

$$
\begin{equation*}
P(u, v, w)=\Sigma \Sigma \Sigma\left|F_{0}(h k \ell)\right|^{2} \cos 2 \pi(h u+k v+\ell w) \tag{7}
\end{equation*}
$$

where $u, v, w$ are the fractional coordinates of the cell at which the function was calculated and $\left|F_{0}(h k \ell)\right|$ is the absolute value of the observed structure factor for the hkl plane. The peaks on a Patterson map correspond to interatomic vectors with the relative height of the peak being proportional to the product of the number of electrons of the two atoms involved. The twenty highest peaks are listed in Table 2.

The calculated height of a $\mathrm{Cu}-\mathrm{Cu}$ peak relative to the origin is 344 . No peaks of this intensity were found on the map so the peak at $0,1 / 2,0$ (relative height 578) was attributed to the $\mathrm{Cu}-\mathrm{Cu}$ vector. The surplus electron density of this peak was thought to be another manifestation of the pseudosymmetry mentioned previously. If we assume the space group $\mathrm{P} \overline{\mathrm{I}}$, then there are two possible sets of copper positions, $0,0,0$ and $0,1 / 2,0$ which are located on centres of symmetry (special positions) or $0,1 / 4,0$ and $0,3 / 4,0$ which are related by centres of symmetry (general positions).

At this stage it was not possible to distinguish between these two possibilities. Two chelate rings could be defined about each copper atom by considering additional Patterson peaks. However, there were three choices for the coordination geometry. These are depicted schematically below. If the copper atoms were located in special positions, then one of

FLATTENED
TETRAHEDRON
the square planar geometries would be present although not necessarily the same one for both positions. On the other hand, if general positions were occupied, the two geometries would be related by a centre of symmetry but any of the three possibilities could be present.

In an effort to find the correct structure, least squares refinement and subsequent Fourier synthesis was attempted for several trial structures. The contributions to the structure factors were calculated by:

$$
\begin{equation*}
F(h k \ell)=\Sigma f_{j} \cos 2 \pi\left(h x_{j}+k y_{j}+\ell z_{j}\right) \exp -\left[B_{j}(\sin \theta / \lambda)^{2}\right] \tag{8}
\end{equation*}
$$

where $x_{j}, y_{j}, z_{j}$ are the fractional coordinates, $f_{j}$ is the scattering factor and $B_{j}$ is the isotropic thermal parameter of the $j$-th atom. The wavelength of the radiation and the Bragg angle of the hkl reflection are respectively $\lambda$ and $\theta$. Ibers and Corfield's version of Busing, Martin and Levy's ORFLS (51) programme was used for the least squares refinement. The computations were performed by a Burroughs 5500 computer. During the refinements, the function that was minimized was $\Sigma \mathrm{w} \Delta^{2}$ where the weight factor is:

$$
\begin{equation*}
\mathrm{w}=1 / \sigma^{2} \quad(\mathrm{~F}) \tag{9}
\end{equation*}
$$

and $\Delta=\left|\left|F_{0}\right|-\left|F_{c}\right|\right|$
The correctness of a structure is usually expressed in terms of weighted
( $R_{2}$ ) and unweighted ( $R_{1}$ ) residual factors defined as:

$$
\begin{align*}
& \mathrm{R}_{1}=\Sigma \Delta / \Sigma\left|\mathrm{F}_{0}\right|  \tag{11}\\
& \mathrm{R}_{2}=\Sigma \mathrm{w} \Delta^{2} / \Sigma \mathrm{w} \mathrm{~F}_{0}^{2} \tag{12}
\end{align*}
$$

For the trial refinements, the overall temperature factor was set to $3.5 \AA^{2}$ and all the ligands were treated as nitrogen atoms.

Fourier syntheses were calculated from observed reflections by:
$\rho(x, y, z)=\Sigma \Sigma \Sigma F(h k \ell) \cos 2 \pi(h x+k y+\ell z)$
using a local version of Zalkin's FORDAP (52). In equation (13), $\rho(x, y, z)$ is the electron density at the point $x, y, z$ in the unit cell and $F$ (hkl) is the observed value of the structure factor of the hkl reflection. Difference Fourier syntheses were computed by subtracting the contributions of the trial atomic positions from the overall electron density Fourier synthesis. Normally, it is possible to determine additional atomic positions from a difference map and thereby solve the complete structure. However, in this case, it was not possible to unequivocally define the coordination geometries nor the positions of the copper atoms. In fact, during these many trial refinements, the R-factor was never less than $37 \%$ which indicated that the actual structure had not been found.

At this point, it was decided to try direct methods as a technique for solving the structure.

## B. Direct Methods

The first attempt at a direct methods solution was made using the X-RAY SYSTEM of crystallographic programmes (53). Implementation of this system on the Burroughs 5500 computer was difficult and only three preliminary programmes were successfully made operational. One of these programmes, NORMSF, produced a list of normalized structure factors or $E$ values defined by:

$$
\begin{equation*}
|E(h k \ell)|=|F(h k \ell)| /\left(\varepsilon \Sigma f_{j}{ }^{2}\right)^{\frac{1}{2}} \tag{14}
\end{equation*}
$$

where $\varepsilon$ is a symmetry related integer equal to one for a triclinic crystal (54). Since the distribution of $E$ values is theoretically and empirically dependent on the presence or absence of a centre of symmetry, it was possible to define the space group as P $\bar{I}$. The list of values on which this conclusion was based are presented in Table 3.

In addition, a sharpened Patterson function was calculated. Previous conclusions were confirmed but no new information was obtained. Further work with the X-RAY SYSTEM was suspended when Sheldrick's SHELX (55) programme became available.

Unfortunately, attempts to produce a decipherable E map using SHELX were equally unsuccessful. It was not known whether the problem was due to the structure or to the programme itself since test runs with data from another structure determination (56) failed to duplicate known results. At one point, the signs of 170 E values greater than 1.2 were determined by hand. However, this set did not include any reflections with odd $k$ indicating that the problems of the pseudosymmetry would not be solved in this manner.

The crystal data were almost discarded as being insoluble when, to further test the programme, a sharpened Patterson map was calculated.

Table 3. Distribution of E Values from NORMSF (X-RAY SYSTEM)
Theoretical Empirical
Centric Acentric

Average Value of

| $\|E\|$ | 0.798 | 0.886 | 0.797 |
| :--- | :--- | :--- | :--- |
| $\left\|E^{2}\right\|$ | 1.00 | 1.00 | 1.00 |
| $\left\|E^{2}-1\right\|$ | 0.968 | 0.736 | 0.953 |
| $\left\|E^{2}-1\right\|^{2}$ | 2.000 | 1.000 | 1.965 |
| $\left\|E^{2}-1\right\|^{3}$ | 8.000 | 2.000 | 9.950 |

## Number of Reflections

With

| $\|E\|>1.0$ | $31.73 \%$ | $36.79 \%$ | $33.99 \%$ |
| :--- | :--- | :--- | :--- |
| $\|E\|>2.0$ | $4.55 \%$ | $1.83 \%$ | $3.93 \%$ |
| $\|E\|>2.5$ | $1.24 \%$ | $0.19 \%$ | $1.09 \%$ |
| $\|E\|>3.0$ | $0.27 \%$ | $0.01 \%$ | $0.20 \%$ |

The results were found to agree with the map obtained from a parallel run with the $X$-RAY SYSTEM (53). A closer examination of this map led to the eventual solution of the structure.

## C. The Sharpened Patterson Map.

The only major technique of structure determination which had not been applied to the data was Patterson superposition. With the thought of trying this technique by hand, the complete Sharpened Patterson map was plotted and is shown in Figure 5. This map was very similar to earlier difference Fourier maps in that the presence of the chelate rings was obvious but exact geometry and further structural features were hard to define.

However, a nitrate group appeared to be present at $u=-1 / 2, v=1 / 2$, $\mathrm{w}=1 / 2$. A trial refinement was attempted with the copper atoms in the special positions and a nitrate group centred on $0.44,0.31,0.52$. The R-factor dropped an expected $8.5 \%$ but more importantly, a second nitrate group centred at $0,1 / 4,1 / 4$ became fully resolved on the difference Fourier map. The presence of this bridging nitrate group confirmed the location of copper atoms in the special positions and served to break the pseudosymmetry.

In order to define the origin consistently, the first nitrate group was ignored and the bridging nitrate group refined isotropically. Again the R-factor dropped $8.5 \%$ but this time structural features were better resolved. In the next stage, both nitrate groups plus two independent chelate rings were refined. The $R$-factor dropped to below $40 \%$ and from the difference map, the positions of all non-hydrogen atoms could be assigned except for one of the hydroxymethyl oxygens. The correctness of these positions was supported by a dramatic drop in the R-factor to $14.77 \%$. The

## FIGURE 5. PLOT OF SHARPENED PATTERSON PEAKS

(FRACTIONAL $V$ COORDINATES ARE IN 26 THS்)

oxygen atom in question was thought to be disordered and in later stages, site occupation factors as well as positional parameters were refined.

## D. Structure Refinement

Following the location of all non-hydrogen atoms, the data set was expanded to include reflections with $2 \theta$ less than $45^{\circ}$. With the complete data set, thermal parameters were converted from isotropic to anisotropic and refined. A subsequent difference map revealed all the hydrogen positions. The isotropic temperature factors for hydrogen atoms were fixed at a value $20 \%$ greater than the thermal parameter of the atom to which it was bonded. A refinement of the hydrogen atom positions reduced the $R$-factor to below $7 \%$.

The final cycles of refinement were postponed while a number of reflections with large $F_{0}-F_{c}$ values were remeasured. At the same time, SHELX (55) was updated and adapted to the Burroughs 6700 computer. In testing the capacities of the new computer and revised SHELX (55) programme, isotropic temperature factors were refined for hydrogen atoms. As expected, the results were unreasonable in their magnitude but assuming that the direction of the change was real, an average value was calculated by $(2 a+b) / 3$ where $a$ is the original value and $b$ is the refined value. In addition, temperature factors were averaged and fixed for similar groups in the two independent molecules. The methyl protons were refined as rigid tetrahedral groups with C-H bond lengths fixed at $1.080 \AA$.

Refinement of the structure continued until the average parameter shift was less than 0.35 estimated standard deviations. In the last cycle, a
total of 397 variables were refined. For the 2390 independent reflections with $F \geq 3 \sigma(F)$, the final $R$ values were $R_{1}=0.0408$ and $R_{2}=0.0431$. A final difference map was calculated and no peaks nor holes with magnitudes greater than 0.4 electrons $\AA^{-3}$ were observed. The values of positional and thermal parameters are presented in Tables 4,5 and 6. Observed and calculated structure factors for all the data are tabulated in Appendix A.

In the final stages of the refinement, the structure factors were weighted according to:

$$
\begin{equation*}
\mathrm{w}=\mathrm{k} /\left(\sigma^{2}(\mathrm{~F})+|\mathrm{g}| \mathrm{F}^{2}\right) \tag{15}
\end{equation*}
$$

where $k$ was determined from refined values of $g$. The final values were $g=0.001062$ and $k=1.6762$. The overall scale factor refined to 1.699 ( $\pm 0.003$ ). The consistency of this weighting scheme was evaluated by an analysis-of-variance technique outlined in Appendix B.

## Table 6. (continued)

Part C. The following hydrogen atoms were part of a disordered hydroxymethyl group attached to the PM molecule associated with $\mathrm{Cu}(1)$. Site occupation factors refined to 0.569 (11) for atoms labelled A and 0.431(11) for atoms labelled B. Positions for $H(9)$ and $H(10)$ were calculated on the basis of the geometry of an hydroxymethyl group. The $H(11)$ atoms were visible on the difference Fourier map and were otherwise refined according to standard procedures.

|  | $x / a$ | $y / b$ | $z / c$ | $10 U+x 10^{3}$ |
| :--- | :--- | :--- | :--- | :--- |
| H(9A) | $340(3)$ | $-187(5)$ | $115(5)$ | 663 |
| H(9B) | $309(3)$ | $-196(6)$ | $122(4)$ | 663 |
| H(10A) | $406(3)$ | $-12(4)$ | $103(5)$ | 663 |
| H(10B) | $430(4)$ | $-178(7)$ | $19(6)$ | 663 |
| H(11A) | $433(7)$ | $-265(11)$ | $73(10)$ | 597 |
| H(11B) | $462(9)$ | $67(15)$ | $128(13)$ | 597 |

$\dagger$ Isotropic temperature factors are given by $\exp \left[-8 \pi^{2} U \sin ^{2} \theta / \lambda^{2}\right]$.

## Chapter IV

Discussion and Results

The overall structure of $\mathrm{Cu}(\mathrm{PM})_{2}\left(\mathrm{NO}_{3}\right)_{2} \cdot \mathrm{H}_{2} \mathrm{O}$ is shown in Figure 6. The view depicted is a projection onto the xy plane followed by a $20^{\circ}$ rotation about $y$ to avoid overlap. $\mathrm{Cu}(1)$ lies at the origin ( $0,0,0$ ) and $\mathrm{Cu}(2)$ at ( $0, \frac{1}{2}, 0$ ) with both atoms located on centres of symmetry. The pseudosymmetry due to these copper positions is reinforced by the fact that many of the remaining atoms are also half a unit cell apart in the y-direction.

Each copper atom is chelated by two centrosymmetrically related PM molecules through the amino groups and deprotonated phenolate oxygen atoms. The presence of zwitterion III (see Figure 4) was further confirmed by the location of protons $H(1)$ and $H(19)$ on the two heterocyclic nitrogen atoms. The two independent $\mathrm{Cu}(\mathrm{PM})_{2}$ moieties are symmetrically bridged by a single oxygen atom from one of the nitrate groups. The second nitrate group is not coordinated to the copper atoms but is central to an extensive hydrogen bonding network involving the water molecule and uncoordinated functional groups of PM. These aspects are discussed in greater detail in the following sections.

## A. The Pyridoxamine Molecules

The bond lengths and angles together with their estimated standard deviations for the two independent pairs of PM molecules are shown in Figures 7 and 8. Angles involving hydrogen atoms are presented in Table 7. From this information, the existence of $P M$ in the zwitterionic form III

* Methy1 protons refined as a rigid group (see Table 6, Part B).
(see Figure 4) can be quickly established. First of all, protons $H(1)$ and $H(13)$ are located on the heterocyclic nitrogen atoms, $N(1)$ and $N(3)$ respectively. Both of these protons were easily found on a difference Fourier map. Secondly, no protons could be located in the region of the two phenolate oxygen atoms.

Both pyridine skeletons are planar within experimental error. For the PM molecule coordinated to $\mathrm{Cu}(1)$, the equation of the mean plane is:

$$
0.5237 X+0.8468 Y+0.0930 Z=1.18119
$$

while the equation for the $P M$ molecule associated with $\mathrm{Cu}(2)$ is:

$$
0.5160 X+0.8566 Y-0.0056 Z=4.8332
$$

The perpendicular distances to these planes for the atoms defining the plane and for substituents on the pyridine rings are presented in Table 8. The average C-C bond length in the ring is $1.393 \AA$. No explanation for significant deviations from this average value (e.g., C(14)-C(16), $1,360(6) \AA$; $C(9)-C(11), 1.414(6) \AA$ ) is offered since there appears to be no consistent correlation with possible resonance structures (see Figure 9). However, differences of similar magnitude have been reported in accurate structure determinations of other pyridine-containing compounds (57, and references cited therein). The average $C-N$ bond length is $1.340 \AA$. The six $C\left(s p^{2}\right)-$ $\mathrm{C}\left(\mathrm{sp}^{3}\right)$ bond lengths have a mean value of $1.511 \AA$. Each of the average values is within the standard range cited for the respective bond types (58).

As a result of protonation, the valence angles at the heterocyclic nitrogen atoms have been distorted. The values of $123.7^{\circ}$ and $123.8^{\circ}$ for $N(1)$ and $N(3)$ respectively are in good agreement with the observations of Singh (59). In a survey of the literature, he found that protonated nitrogen atoms in six-membered heterocycles had angles in the range of $125 \pm 3^{\circ}$ while unprotonated species had angles in the range of $116 \pm 3^{\circ}$. This

PROTONATED PHENOLATE GROUP
phenomenon has also been observed in crystal structures of other compounds related to vitamin $B_{6}$ and can be used to determine protonation sites although the protons themselves were not necessarily located (31,60-63).

Another structural feature of interest involves the phenolate oxygen atoms. The bond lengths of 1.307 and $1.314 \AA$ for $C(3)-0(1)$ and $C(11)-0(3)$ respectively are similar to the values of 1.28 and $1.30 \AA$ which were found in a metal-Schiff base complex where the phenolate oxygen was coordinated to $\mathrm{Ni}(\mathrm{II})$ (31). In contrast to these values are the somewhat longer distances of 1.34 to $1.35 \AA$ recorded for structures in which the phenolate oxygen atom was protonated (60-63). An explanation for this difference can be found by considering the resonance forms shown in Figure 9. From the short C-0 bond lengths and valence angles of approximately $120^{\circ}$ observed in this structure and in the Ni(II) Schiff base complex (31), it would appear that forms III, IV and V make significant contributions to the observed structures where the phenolate oxygen atoms are deprotonated. On the other hand, similar resonance structures, VII, IX and X, for protonated phenolate groups would involve the location of an unstable positive formal charge on the oxygen atom. Therefore, such forms would be expected to make relatively small contributions to the overall structure, resulting in a longer $\mathrm{C}-\mathrm{O}$ bond.

## B. Copper Coordination

The two independent copper atoms are located at centres of symmetry at $(0,0,0)$ and $\left(0, \frac{1}{2}, 0\right)$. The coordinated ligands define a tetragonally distorted octahedron. Distances are shown in Figure 10 and relevant angles are presented in Table 9. The amino nitrogen atom, $\mathrm{N}(2)$, and the phenolate oxygen atom, $O(1)$, from one $P M$ molecule together with the correspond-

The equation of the plane defined by the nitrate group is:

$$
0.7033 \mathrm{X}+0.7106 \mathrm{Y}+0.0206 \mathrm{Z}=1.5179
$$

The equation of the plane defined by $\mathrm{Cu}(1)-0(5)-\mathrm{Cu}(2)$ is:

$$
1.0000 \mathrm{X}+0.0000 \mathrm{Y}-0.0030 \mathrm{Z}=0.0000
$$

The dihedral angle between the above planes is $45.3^{\circ}$.

* Atoms defining the plane
ing pair of atoms from the centrosymmetrically related PM molecule define a slightly distorted square plane at $\mathrm{Cu}(1)$. A similar but independent square plane is defined at $\mathrm{Cu}(2)$ by $\mathrm{N}(4)$ and $\mathrm{O}(3)$. The intrachelate $\mathrm{N}-\mathrm{Cu}-0$ angles, $92.2^{\circ}$ and $92.9^{\circ}$ respectively, are very close to the ideal value of $90^{\circ}$. The distortion from a perfect square is also marked by a difference of $0.1 \AA$ between the $\mathrm{N}-\mathrm{O}$ and $\mathrm{N}-\mathrm{O}^{\prime}$ separations (see Table 9). These variations can be attributed to the difference in ligands and the constraints of the six-membered chelate rings. Metal-ligand bond lengths are similar to values found in other structures (64).

The octahedral sites of both copper atoms are occupied by a single nitrate oxygen atom, $0(5)$. Since the $\mathrm{Cu}-\mathrm{O}(5)$ bond lengths differ from the bond lengths found in the square plane, the coordination at each copper atom may be described as $(4+2)(64)$. The tetragonal distortion present here is of the type usually observed when Jahn-Teller effects are operative in octahedral complexes (64). However, the type of nitrate-oxygen bridge found in this structure is not so common. Only three other examples of this type of bridging nitrate group could be found in the literature: $\alpha-\mathrm{Cu}\left(\mathrm{NO}_{3}\right)_{2}(65)$, $\left[\mathrm{Cu}\left(\mathrm{NO}_{3}\right)_{2} \mathrm{py}_{2}\right]_{2 \mathrm{py}},(\mathrm{py}=$ pyridine $)(66)$ and $\left[\mathrm{Ag}\left\{\mathrm{P}(\mathrm{OMe})_{3}\right\}_{2} \mathrm{NO}_{3}\right]_{2}$ (67). In each case, a nonbridging oxygen atom was also coordinated to the metal atom, either strongly (2.02 $\AA$, 65) or weakly ( $2.90 \AA, 66 ; 3.01 \AA, 67$ ). The net result was that the metal ion undergoing the additional bonding is very close to the plane of the nitrate group while the second metal atom in the bridged unit is much further removed from the plane.

In the present structure, neither of the nonbridging oxygen atoms interacts with the copper atoms: the $\mathrm{Cu}(1)-0(6)$ and $\mathrm{Cu}(2)-0(7)$ distances are 3.483 and $3.616 \AA$ respectively. Furthermore, the nitrate group is
twisted by $44.7^{\circ}$ about the $O(5)-N(5)$ bond so that the $\mathrm{Cu}(1)$ and $\mathrm{Cu}(2)$ atoms are located more than $1.51 \AA$ from the nitrate plane, on opposite sides. This twisting of the nitrate group is quite surprizing for two reasons. First of all, the $N(2)-0(5)$ bond length of $1.255 \AA$ and the $\mathrm{Cu}(1)-0(5)-\mathrm{Cu}(2)$ bond angle of $117.3^{\circ}$ indicate that the $O(5)$ atom is $\mathrm{sp}^{2}$-hybridized. Thus, the copper atoms would be expected to be in the plane of the nitrate group to establish maximum overlap between the lone electron pairs from 0 (5) and the orbitals on $\mathrm{Cu}(1)$ and $\mathrm{Cu}(2)$. Secondly, coplanarity would minimize any steric crowding of the nitrate group by the two $\mathrm{Cu}(\mathrm{PM})_{2}$ moieties. However, these considerations appear to have been overshadowed by the formation of two hydrogen bonds which is made possible by the twisting. The relevant distances are $2.225 \AA$ for $0(6) \ldots H(8)$ and $2.243 \AA$ for $0(7) \ldots H(19)^{\prime}$ (see also Table 9).

A final noteworthy feature of the copper coordination is the conformation of the chelate rings. In the six-membered ring incorporating $\mathrm{Cu}(1)$, the metal atom, $N(2), C(3)$ and $C(4)$ are coplanar within experimental error while $O(1)$ and $C(5)$ are 0.4348 and $0.6453 \AA$ above the plane respectively. The resulting boat conformation is distorted since two of the six bonds are considerably longer than the other four. A similar boat can be defined at $\mathrm{Cu}(2)$ with $\mathrm{O}(3)$ and $\mathrm{N}(4)$ being 0.4296 and $0.6752 \AA$ below the plane (see Table 9).

Six-membered chelate rings have been found to exist in boat conformations for a series of metal complexes of 2(2-aminoethyl)pyridines (57 and references cited therein). In these compounds, the metal atom occupies one of the two "flagpole" positions which is not the case in this structure. The difference in conformations can be attributed to the formation of hydrogen bonds to the bridging nitrate (vide supra) as well as an additional inter-
action involving the phenolate and amino groups. The oxygen atoms coordinated to one copper atom are hydrogen bonded to the amino protons associated with the other metal atom (see Figure 10 and Table 9). These interactions together with the hydrogen bonds to $O(6)$ and $O(7)$ create a sheath surrounding the infinite chain defined by the copper atoms and the bridging nitrate group. Linkages between these columns, which are aligned in the $y$ direction, will be described in the next section.

Although $\mathrm{Cu}(1)$ and $\mathrm{Cu}(2)$ are not related crystallographically, the chemical environments of both metal centres are very similar. This similarity extends to the surrounding hydrogen bonding network (see Figure 10). For example, the amino protons, $H(19)$ and $H(20)$ undergo interactions which parallel those found for $H(7)$ and $H(8)$ on the independent amino group. This reciprocal arrangement between independent atoms in this structure is very striking and accounts for some of the difficulty in solving the Patterson map (vide supra).

## C. Molecular Packing

The dominant feature of molecular packing is the sheath of interactions surrounding the infinite chain formed by the copper atoms and bridging nitrate groups. This series of bonds and hydrogen bonds is shown in Figure 10 and fully described in the preceding section. The cross-linkage between these columns is of two types with each type associated with layers formed by each of the independent copper atoms. A brief description of each type will be followed by a discussion of the participating hydrogen bonds. A final paragraph will deal with the disordered hydroxymethyl group.

Firstly, the $\mathrm{Cu}(1)$ complex at $(0,0,0)$ is diagonally connected to the $\mathrm{Cu}(1)$ complex at ( $1,0,-1$ ). The protonated heterocyclic nitrogen atoms,
$N(1)$ and $N(3)^{\prime}$, of the $P M$ molecules coordinated to the respective copper atoms are hydrogen bonded (see Figure 11) to two centrosymmetrically related water molecules $O(11)$ and $O(11)^{\prime}$. These in turn are doubly linked by a pair of (uncoordinated) nitrate groups which are related by the same centre of symmetry. The importance of this "ring-like" structure of nitrate and water molecules is described below. A schematic of this first type of intercolumn linkage is shown in Figure 12.

The second type of cross-linkage joins $\mathrm{Cu}(2)$ complexes related by translation in the $z$ direction. The protonated heterocyclic nitrogen atom of one PM molecule is connected to the hydroxymethyl group of the next by means of a nitrate oxygen atom, $0(10)$. A second interaction of this type is generated by the centre of symmetry at $\left(0, \frac{1}{2}, \frac{1}{2}\right)$. The (uncoordinated) nitrate group linking $\mathrm{Cu}(2)$ complexes also forms the ring of interactions with the water molecules (vide supra). Thus the translational $\mathrm{Cu}(2)$ series is connected to the diagonal $\mathrm{Cu}(1)$ series. In addition, the $\mathrm{Cu}(2)$ string at $\left(0, \frac{1}{2}, z\right)$ is joined diagonally to a parallel series at ( $1,-\frac{1}{2}, z$ ) through the same ring structure. Both the translational and diagonal connections involving $\mathrm{Cu}(2)$ complexes are illustrated in Figure 12.

The above interactions are shown in greater detail in Figure 11. The view is a projection onto the $x z$ plane with the primed atoms related to the unprimed by a centre of symmetry at $\left(\frac{1}{2}, 0, \frac{1}{2}\right)$. To establish perspective in this figure, the linkage from $O(4)$ through $O(10)$ to $N(3)$ is more or less in the plane of $y=\frac{1}{2}$. The $N(1), O(11), O(11)^{\prime}$ and $N(1)^{\prime}$ atoms are distributed about $\mathrm{y}=0$ while the $\mathrm{O}(4)^{\prime}-\mathrm{O}(10)^{\prime}-\mathrm{N}(13)^{\prime}$ link is at $\mathrm{y}=-\frac{1}{2}$. The primed and unprimed nitrate groups are located at $y=\frac{1}{4}$ and $y=-\frac{1}{4}$ respectively. Relevant distances and angles are listed in Table 10.

FIGURE 12. SCHEMATIC DIAGRAMS OF INTERCOLUMN LINKAGES

As shown in Figure 11, the primed and unprimed nitrate groups are doubly bridged by centrosymmetrically related water molecules. The hydrogen bonds involving $H(25)$ and $H(26)$ are within the standard range (58). The oxygen atoms of the water molecules are tightly hydrogen bonded to the protonated heterocyclic nitrogen atoms of PM molecules coordinated to $\mathrm{Cu}(1)$ atoms. The $N(1)-O(11)$ separation of $2.727 \AA$ is actually less than the sum of van der Waal's radii for nitrogen and oxygen (2.9 A ) . A very short contact also characterizes the protonated nitrogen atom in the independent PM molecule $(N(3)-0(10), 2.822 \AA)$. The ability of these protonated heterocyclic nitrogen atoms to form very strong hydrogen bonds is consistent with the importance of this group in the binding of the coenzyme to the enzyme (10). The remaining contact (2.103 A) between $H(23)$ and $O(10)$ is within standard values (58).

Finally, the disorder of the hydroxymethyl group attached to $C(6)$ can be attributed to the fact that this group can participate in two different hydrogen bonds. In the most populated orientation (site occupation factor of 0.569$), \mathrm{H}(11 \mathrm{~A})$ is $1.935 \AA$ away from $0(4)$. This contact is shown in Figure 6. The second orientation involves a contact of $2.125 \AA$ between $O(2 B)$ and $H(26)$ and is not illustrated. The differences in the population distribution of these two orientations is probably due to the relative strengths of the hydrogen bonds which are formed in each case.

Chapter V
Conclusion

The crystal structure of a copper II complex with the pyridoxamine form of vitamin $B_{6}$ has been determined. In the complex, the metal atoms are chelated by methyl amino and deprotonated phenolate oxygen groups. The rigid square planar geometry defined by these atoms is consistent with both the inability of copper to assist in Schiff base formation (21) and the catalytic effectiveness of copper in model transamination and similar reactions (31) (vide supra). This is in contrast to natural systems where the enzyme is active in both reactions.

Also in this complex, the zwitterionic form of pyridoxamine was found to involve deprotonation of the phenolic group and protonation of the heterocyclic nitrogen atom. This form is different from that thought to be the dominant species in solution (34). However, protonation of the heterocyclic nitrogen atom is important in enzymatic systems, both as an electron sink and binding site (12). Since the former aspect is also important in model reactions, the metal ion in vitro may duplicate an enzymatic function by inducing the required zwitterionic structure through chelate formation.

Finally, the two independent copper complexes in this structure are bridged by a single nitrate oxygen atom. This bridge appears to be unique (65-67) in that neither of the nonbridging nitrate oxygen atoms interacts with a metal atom. Consequently, the formation of relatively weak hydrogen bonds has resulted in a large angle ( $45^{\circ}$ ) between the plane of the nitrate molecule and that defined by the copper atoms and bridging oxygen atom.

## APPENDIX B

THE CONSISTENCY OF WEIGHTS

It is possible to test the consistency of a weighting scheme by considering the standard deviation, $S$, of a reflection of unit weight. The SHELX programme provides a table of variance values defined as:

$$
\mathrm{V}=100 * \mathrm{~S}=100 *\left[\mathrm{M} * \sum_{1}^{N}(\mathrm{w})\left(\mathrm{F}-\mathrm{F}_{\mathrm{c}}\right)^{2} / \mathrm{N} * \sum_{1}^{\mathrm{M}}(\mathrm{w})\right]^{\frac{1}{2}}
$$

where $N$ is the number of reflections in the group, $M$ is the total number of reflections and $w$ is the weight factor. These values are presented in Table B.1. If the weights are satisfactory, it is expected that $S$ would be distributed as $\chi^{2} /(n-m)$ for $n-m$ degrees of freedom (1). That is,

$$
\frac{x_{n}^{2}-m, 1-\alpha}{n-m}<s<\frac{x_{n}^{2}-m, \alpha}{n-m}
$$

In this structure, there are 2390 observations defining 397 variables and therefore $2390-397=1993$ degrees of freedom. For more than 100 degrees of freedom, the values of $x_{n}^{2}-m, 0.99$ may be approximated by the expression (2): $\frac{1}{2}\left[(2(n-m)-1)^{\frac{1}{2}}+2.33\right]^{2}$. Thus,

$$
x_{1993,0.99}^{2}=\frac{1}{2}\left[(2 * 1993-1)^{\frac{1}{2}}+2.33\right]^{2}=2142
$$

and

$$
\frac{x_{1993,}^{2} 0.99}{1993}=1.07
$$

1. W. C. Hamilton in International Tables for X-ray Crystallography,

Vol. IV, the Kynoch Press, Birmingham, England (1974). p 293.
2. E. Kreyszig, Advanced Engineering Mathematics , 3rd ed., John Wiley and Sons, Inc., Toronto, Canada (1972). p 843.

Similarly,

$$
\begin{aligned}
x_{1993,0.01}^{2} & =\frac{1}{2}\left[(2 * 1993-1)^{\frac{1}{2}}-2.33\right]^{2} \\
& =1848
\end{aligned}
$$

and

$$
\frac{x_{1993,0.01}^{2}}{1993}=0.93
$$

Therefore, the condition, $0.93<\mathrm{S}<1.07$, should hold.
From the table of values produced by SHELX (Table B.1), it can be seen that $S=0.95$ for all the data. From this, it was concluded that the overall weighting scheme was satisfactory. However, the value of $S$ should also be independent of the choice of subset and this criterion is not fully satisfied. In the following paragraphs, possible causes for a number of the values outside the desired range are discussed.

First of all, the value of $S$ appears to be correlated to the parity of $k$. Reflections with even $k$ values tend to have $S$ less than 0.93. In other words, the odd $k$ reflections have been systematically overweighted. This correlation is a result of the pseudosymmetry with respect to the $y$ axis but it was not thought to be a serious problem.

As expected, there is no systematic distinction between the data collected from $0^{\circ}$ to $35^{\circ}$ and the set, $35^{\circ}$ to $45^{\circ}$, which was collected later (see SIN THETA table). However, low angle reflections, which are generally more intense as well, tend to be somewhat overweighted. This correlation was thought to result from the fact that no corrections were made for extinction. Intense, low angle reflections are particularly susceptible to extinction which is due to multiple internal reflections of the x-rays. However, after examination of observed and calculated
structure factors, it was found that extinction affected very few, if any, reflections. Therefore, either extinction has not caused the correlation or, if it has, the effect is very small.

As a third group, the weaker reflections seem to be underweighted (see SQRT(F/FMAX) table). This implies that $\sigma$ is large for these reflections which is to be expected since $\sigma$ varies as $1 / \sqrt{I}$ where $I$ is the relative intensity.

In conclusion, the overall weighting scheme was termed satisfactory and apparent systematic deviations were not of sufficient magnitude to warrant further revision.
