## Abstract

This investigation comprises a comparison of experimental and theoretical dechanneling of MeV protons in copper single crystals. Dechanneling results when an ion's transverse energy increases to the value where the ion can undergo small impact parameter collisions with individual atoms. Depth dependent dechanneling rates were determined as functions of lattice temperature, ion beam energy and crystal axis orientation. Ion beam energies were 1 MeV and 2 MeV ,temperatures ranged from 35 K to 280 K and the experiment was carried out along both the $\langle 100\rangle$ and $\langle 110\rangle$ axes.

Experimental data took the form of aligned and random Rutherford backscattered energy spectra. Dechanneling rates were extracted from these spectra using a single scattering theory that took explicit account of the different stopping powers experienced by channeled and dechanneled ions and also included a correction factor to take into account multiple scattering effects along the ion's trajectory.

The assumption of statistical equilibrium and small angle scattering of the channeled ions allows a description of dechanneling in terms of the solution of a diffusion like equation which contains a so called diffusion function. The diffusion function is shown to be related to the increase in average transverse energy. Theoretical treatments of increase in average transverse energy due to collisions of projectiles with channel electrons and thermal perturbations in the lattice potential are reviewed. Using the diffusion equation and the electron density in the channel centre as a fitting parameter dechanneling rates are extracted.

Excellent agreement between theory and experiment has been demonstrated. Electron densities determined in the fitting procedure appear to be realistic. The surface parameters show themselves to be good indicators of the quality of the crystal.

## Acknowledgements

The author would like to express his most sincere appreciation to Dr. J.A. Moore for supervising this thesis and Dr. L.M. Howe for participating in the experimental investigation and calculating the theoretical dechanneling rates.

The award of OGS fellowship and the financial assistance from NSERC is gratefully acknowledged.

My thanks to Mr. T. Quenneville for his technical help regarding the polishing of crystals; I also thank the institutions of Guelph University and Chalk River Nuclear Laboratories for allowing me access to their facilities.

I would like to express my appreciation to my spouse Rita and my family for their support and understanding throughout my studies.

## 1. Introduction

MeV and keV ion beams can be used for analysing and modifying physical properties within several microns of a solid's surface. Modifications may be affected through controlled implantation of ion species. For example: crystalline structure can be made amorphous and doping can be carried out in semiconductor manufacturing. Analyses can be performed using the ability to determine mass, concentration and location of atoms using the techniques of Rutherford backscattering (RBS), nuclear reactions and channeling. Atom location techniques, for example, require channeling of ions along major crystallographic axes of a single crystal and then the atom's position within the lattice can be deduced from the resultant spectra.

### 1.1 Background

Consider an ion beam incident upon a single crystal, with energy E。, along a major crystallographic direction. To the beam, there appears an array of atomic strings parallel to the axis with end points being the surface atoms. To a first approximation the ion beam is assumed to interact with an infinite single string of atoms. An incident angle, $\boldsymbol{\phi}$, can be defined as that angle between the direction of the beam and crystallographic axis.

The approximation to the potential of a Thomas-Fermi, T-F, atom used by Lindhard ${ }^{7}$ to derive an expression for the effective interaction between a single string and an ion whose trajectory is almost parallel to the string is given as

$$
V(R)=\frac{Z 1 Z 2 e^{2}}{R}\left(1-\left(1+(C a / R)^{2}\right)^{-\frac{1}{2}}\right) \quad 1.1 .1
$$

Where $\mathrm{Z1}, \mathrm{Z2}$ are ion and lattice atom atomic numbers, R is the distance from a lattice atom, $C$ is a constant with a value of $\sqrt{3}$, a is the $T-F$ screening distance. By integrating equation 1.1.1 along the string's axis the standard continuum potential $U(r)$ is obtained

$$
\mathrm{U}(\mathrm{r})=\frac{\mathrm{Z1} \mathrm{Z2} \mathrm{e}^{2}}{\mathrm{~d}} \ln \left(1+(\mathrm{Ca} / \mathrm{r})^{2}\right)
$$

Where $d$ is the axial lattice spacing, and $r$ is the radial distance perpendicular to the string. This can be looked upon as an averaging of the discrete spherical atomic charge distributions into a continuum with a cylindrically symnetric charge distribution.

Trajectories can be described by the standard continuum potential if an ion's trajectory at the channel centre with respect to the string is less than a critical angle defined as

$$
\psi_{1}=\sqrt{2 \mathrm{Z1} \mathrm{Z2} \mathrm{e}}
$$

If not, the projectile may, through small impact parameter collisions with individual atoms in the string, undergo large angle scattering.

For ions under the influence of the potential $U(r)$, their velocities parallel to the string are constant and it is thus necessary that energy in the direction perpendicular to the string, called the transverse energy, be conserved. Thus it is convenient to study the three dimensional motion of ions as a projection on a two dimensional plane perpendicular to the string. The parameter of interest now being the transverse energy, $E_{\perp}$, which can be calculated as follows

$$
E_{\perp}=K_{\perp}+U(r) \quad 1.1 .4
$$

Where $K_{\perp}$ is the transverse kinetic energy.

Ideally, two regimes of projectile energies can be defined with respect to the critical transverse energy $E_{\mathcal{L}_{,}}\left(=\psi_{1}^{2} E_{0}\right)$ :
i...Channeled fraction

Those projectiles with transverse energies less than the critical transverse energy; they are steered away from the string and will thus be precluded from small impact parameter/large angle scattering collisions.
ii... Random fraction

Those projectiles with transverse energies greater than the critical transverse energy; they interact normally with the lattice and may undergo large angle scattering as a result of small impact parameter collisions.

In reality, a channeled ion scatters from thermally vibrating lattice atoms and individual electrons. In an individual collision an ion may scatter to higher or to lower transverse energy. Since the initial distribution is peaked towards low transverse energies it is expected that the transverse energy distribution will broaden and thus the average transverse energy of the beam will tend to increase with depth. Theoretically, the change in transverse energy distribution with depth is given by solving a diffusion-like equation. The corresponding changes to the transverse energies are controlled mainly by electron collisions within the channel and with thermally vibrating string nuclei. Due to these scatterings, a channeled ion's transverse energy can increase to the point where it makes a transition from the channeled to the random fraction, i.e. the ion is dechanneled. Once part of the random fraction, an ion interacts normally with the lattice and may therefore undergo large angle elastic scattering.

Experimentally, the increase in dechanneled fraction with depth may be observed using RBS techniques . For a well aligned beam/crystal axis system the increase in average transverse energy with depth, which brings increasing numbers of ions into the random fraction, is seen in a backscattered spectrum as an increase in the aligned yield with depth, figure 1.l. If an amorphous solid of the same material were used then the ions would interact normally with all atoms. The backscattered yield for an amorphous solid quickly rises to the bulk value in the surface region; the slight increase in yield with depth is partially due to the change in differential scattering cross section as a function of energy, figure 1.1.

figure I.I: schematic backscattered spectra

Dechanneled fractions can be extracted from these spectra and may then be compared with theoretically determined values.

### 1.2 Previous Work

In 1965 Lindhard ${ }^{7}$ developed and used a continuum model to describe the net effect of scattering by electrons and atoms on channeled ions． This led to a diffusion－like equation whose solution describes the depth dependent transverse energy distribution for a group of projectiles．Since then several papers have been published dealing with significant improvements in treatment of nuclear and electronic scattering．Numerical solutions of the diffusion－like equation have led to theoretical determinations of the dechanneled fraction．

Thus far，experiment and theory have been investigated for silicon，germanium，tungsten and gold single crystals．Passing reference has also been made about iron，niobium，molybdenum and tantalum crystals as well．

In 1972 Bonderup et al $^{8}$ ，solving Lindhard＇s equations numerically， found that theoretical values for the dechanneled fractions were $a$ factor of three lower than the experimental values for 1.6 MeV protons along the 〈110〉 axis of silicon at $20^{\circ} \mathrm{C}$ and $700^{\circ} \mathrm{C}$ ．The authors knew that the nuclear and electronic scattering contributions were based on rather cursory estimates and likely needed modification．

In 1973 Shiott et al modified equations in the previous paper by including a more realistic electron density in the channel centre and by taking into account terms in the nuclear scattering of higher order than Lindhard＇s first order analysis．Also in 1973 Pederson et al ${ }^{10}$ ， based on Shiott＇s modifications，found the following：For both 1.6 MeV protons along the 〈110〉 axis of silicon and 2.0 MeV protons along the $\langle 100\rangle$ axis of tungsten agreement was excellent at $20^{\circ} \mathrm{C}$ and deviated by up to $20 \%$ by the $700^{\circ} \mathrm{C}$ run．For several runs on tungsten down other
axes they found good agreement．On iron，niobium，molybdenum and tantalum theoretical values were a factor of 1.5 to 2 lower．They suggested that this might be attributed to large concentrations of defects．

In 1980 Matsunami and Howe＂treated the nuclear term in a slightly different manner by adding in a high transverse energy contribution ${ }^{12}$ to Lindhard＇s first order term．The electronic term was modified by taking into account the geometry of the channel using a multi－string formulation，and by using the electron density at the channel centre as a fitting parameter．They found for both 1.6 MeV and 2.0 MeV protons in silicon and germanium respectively along the $\langle 110\rangle$ and〈111〉 axes that agreement with experiment was good with deviations of $10-20 \%$ at shallow depths and $10 \%$ at greater depths．These were performed at temperatures ranging from 293 K to 973 K ．

In 1980 Moore ${ }^{13}$ developed a method for analysing experimental data which took into account different rates of energy loss for channeled and random fraction ions，variation of stopping powers and stopping cross sections with energy and deviation of backscattered spectra from single scattering theory．In this method it has been recognized that there is no unique trajectory associated with the backscattered yield at a particular energy．By taking this into consideration better representations of experimental dechanneled fractions may be obtained．

Recently，1983，Howe et al ${ }^{14}$ applied the theoretical method of Matsunami and Howe＂with the Moore ${ }^{13}$ treatment of experimental spectra to the interpretation of gold dechanneling data．The results for $0.5-2.0$ MeV protons along 〈110〉 axis at temperatures from 35 K to 275 K were that theory and experiment matched to within $10 \%$ ．

### 1.3 Thesis Topic

This thesis will concern itself with the extraction of experimental and comparison with theoretical dechanneling rates for copper single crystals; estimates of electron densities in the channel centre for the two axes investigated will also result. The study comprises an investigation of the dependence of the dechanneled fraction on lattice temperature, ion beam energy and axial direction. The theoretical treatment will be based on the latest model of Matsunami and Howe " which treats dechanneling as a diffusion problem and which includes the electron density in the channel centre as a fitting parameter. The experimental data will be analysed using a method developed by Moore ${ }^{13}$ which explicitly takes into account the different stopping powers experienced by channeled and dechanneled ions.

Given the fact that only the 1983 paper ${ }^{14}$ has been investigated utilizing the more accurate treatment of experimental data it was felt that further investigations were necessary in order to extend the domain of validity of the theoretical model and treatment of the experimental data. Copper was chosen for it's availability as a high quality single crystal and the fact that it's dechanneling data has not been evaluated using the newest techniques. Copper has properties similar to but sufficiently different from those systems already studied, eg. atomic mass, debye temperature etc., that further dechanneling information may be useful when looking for trends.

## 2. Theoretical Dechanneling: Introduction

This chapter is an overview of dechanneling theory based on an analysis of the four most significant papers starting from Lindhard's ${ }^{7}$ classic 1965 work to Matsunami and Howe's research in 1980.

When the functional relationship of the depth-transverse energy distribution, $g\left(E_{\perp}, z\right)$, is known it becomes possible to extract the dechanneled fraction, $X(z)$, as a function of depth $z$. This is performed by integrating the product of this distribution with a nuclear scattering (also refered to as close encounter or small impact parameter) probability function, $\pi$, over transverse energy, we get the following
$X(z)=\int d E_{\perp} g\left(E_{\perp}, z\right) \pi\left(E_{\perp}\right) \quad 2 \cdot .1$

The close encounter nuclear scattering probability function approaches zero for well channeled ions and one for the random fraction; it can be approximated as a step function, written as

$$
\pi\left(E_{\perp}\right)=\begin{array}{ll}
0 & E_{\perp}<E_{\perp, c} \\
1 & E_{\perp}>E_{\perp, c}
\end{array} \quad \text { 2. .2 }
$$

Thus, in this two beam model, the problem of calculating a dechanneled fraction is completely specified by the determination of the depth-transverse energy distribution function.
2.1 Dechanneling Theory

A beam of ions incident upon a crystal along a crystallographic axis will have an initial transverse energy distribution due to collimation, beam/axis alignment and impact parameter distribution. This distribution in phase space, however, will not be in statistical
equilibrium.
For a perfectly collimated beam at zero depth the initial transverse energy distribution is given by
$g\left(E_{\perp}, 0\right) d E_{\perp}=d\left(r^{2}\right) / r_{0}^{2}$

$$
2.1 .0
$$

Where $r$ is the radius of the transverse unit cell area per string and can be defined with respect to atomic density, $N$, and axial lattice constant, d , as $\pi r_{0}^{2}=1 / \mathrm{d} N$ (overlap of unit cells being ignored). And, $E_{\perp}$ is equal to $E \boldsymbol{\phi}^{2}+U(r)$.

At zero depth, a group of particles on an energy shell $E_{\perp}$ to $E_{\perp}+\mathrm{dE}_{\perp}$ has a real space distribution in the transverse plane as represented in figure 2.1 and a momentum space distribution as in
figure 2.2. $\uparrow$

figure 2.1: real space distribution

figure 2.2: momentum space distribution

As this group penetrates the crystal it would be expected that the phase space distribution would become modified due to successive scatterings from the continuum strings. Statistical mechanics suggests that an equilibrium distribution will be achieved.

By considering elastic scattering collisions of ions with strings, randomly distributed in the transverse plane, Lindhard ${ }^{7}$ estimated the depth at which statistical equilibrium would be reached to be roughly 1000 atomic layers, or, after an energy loss of 1 to 10 keV.

For this group of particles, which have attained statistical equilibrium, what is their spatial distribution in the transverse plane?

This group of particles obeys a conservation equation in terms of the transverse energy, and is written as

$$
E_{\perp}=p_{\perp}^{2} / 2 m+U(r)
$$

Corresponding to a point in transverse real space, the accessible area in transverse momentum space is $2 \pi p_{\perp} d p_{\perp}$, where, using 2.1.1 we find

$$
2 \pi \mathrm{p}_{\perp} \mathrm{dp}=2 \pi \mathrm{md} E_{\perp}=\text { constant }
$$

Hence, for particles in statistical equilibrium, each accessible point in real space is equally probable. Thus particles with transverse energy in the range $E_{\perp}$ to $E_{\perp}+d E_{\perp}$ are uniformly distributed across the accessible area in the transverse plane. The accessible area is given by $A\left(E_{\perp}\right)=\pi\left(r_{0}^{2}-\hat{r}^{2}\right)$ and $\hat{r}$, the distance of closest approach, is given by $E_{\perp}=U(\hat{r})$.

Now introduced into this idealized system of elastic collisions between ions and the standard string potential is the realism of thermally vibrating lattice atoms along with electrons which act as scattering centres. These scatterings will have the effect of altering the transverse energy distribution of the beam as a function of depth.

At a point $r$ in transverse real space, for a particle of energy $\mathrm{E}_{\perp}$ which scatters into an interval $\mathrm{dE}_{\perp}^{\prime}$ about energy $E_{\perp}^{\prime}$, the probability of scattering can be written as $p_{r}\left(E_{\perp}^{\prime}, E_{\perp}\right) d E_{\perp}^{\prime}$. The group of particles with
transverse energy $E_{\perp}$, having reached statistical equilibrium, have an areal probability distribution that is independent of depth. Thus when averaging over the accessible area the probability of scattering from $E_{\perp}$ to $E_{\perp}^{\prime}$, over a path length $d z$, will be independent of depth and can be written as $d z p\left(E_{\perp}^{\prime}, E_{\perp}\right) d E_{\perp}^{\prime}$.

In this situation, an equation can be written from which the transverse energy distribution function, $g\left(E_{\perp}, z\right)$, can be extracted. The equation for the transverse energy distribution as a function of depth is written as

```
g(E E , z) dE [ 
    + probability flux in 2.1.3
    - probability flux out
```

In terms of the scattering probability, 2.1 .3 can be written as

$$
\begin{align*}
g\left(E_{\perp}, z\right) d E_{\perp}= & g\left(E_{\perp}, z-d z\right) d E_{\perp} \\
& +\int d E_{\perp}^{\prime} g\left(E_{\perp}^{\prime}, z-d z\right) p\left(E_{\perp}, E_{\perp}^{\prime}\right) d z d E_{\perp} \\
& -\int d E_{\perp} g\left(E_{\perp}, z-d z\right) p\left(E_{\perp}^{\prime}, E_{\perp}\right) d z d E_{\perp}^{\prime}
\end{align*}
$$

Letting dz $\rightarrow 0$ yields

$$
\frac{\partial g\left(E_{\perp}, z\right)}{\partial z}=\int d E_{\perp}^{\prime}\left\{p\left(E_{\perp}, E_{\perp}^{\prime}\right) g\left(E_{\perp}^{\prime}, z\right)-p\left(E_{\perp}^{\prime}, E_{\perp}\right) g\left(E_{\perp}, z\right)\right\} \quad 2.1 .5
$$

Utilizing the fact that the scattering probability function is highly peaked towards very small values in energy transfer $\hat{E}_{\perp}=E_{\perp}^{\prime}-E_{\perp}$, Bonderup et al performed a Taylor series expansion on equation 2.1.5 with the final result being a diffusion-like equation, as shown below

$$
\frac{\partial g\left(E_{\perp}, z\right)}{\partial z}=\frac{\partial}{\partial E_{\perp}}\left\{D\left(E_{\perp}\right) \frac{\partial}{\partial E_{\perp}}\left(g\left(E_{\perp}, z\right)\right)\right\}
$$

The factor $D\left(E_{\perp}\right)$, called the diffusion function, is given by

$$
D\left(E_{\perp}\right)=\frac{1}{2} \int d \hat{E}_{2} \hat{E}_{\perp}^{2} \tilde{p}\left(E_{\perp},\left|\hat{E}_{\perp}\right|\right)
$$

Where $\tilde{p}\left(E_{\perp},\left|\hat{E}_{\perp}\right|\right)$ is the probability per unit energy per unit length of a particle undergoing an energy transfer $\hat{E}_{\mathcal{L}}$ to or from energy $E_{\perp}$. Through this parameter information about the physical attributes of the scattering system are passed to the diffusion equation, 2.1.6.

Equations 2.1 .6 and 2.1 .7 apply to the case of small transverse energy since then accessible area is approximately a constant.

The diffusion function $D\left(E_{\perp}\right)$ is, physically, the mean square transverse energy transfer per unit length and it is a function of transverse energy, independent of transverse energy distribution and depth.

It might be expected that to determine $D\left(E_{\perp}\right)$ a knowledge of the transition probability as a function of both transverse energy and energy transfer would be required. However, it is possible to utilize the small angle scattering information implicitly available through the stopping power and which is well modeled theoretically for monoenergetic ions to determine the diffusion function.

Consider a group of channeled ions, energy $E_{\alpha}^{0}$ at depth $z_{0}$, which are in statistical equilibrium and therefore uniformly distributed across the accessible area in the transverse plane. Their change in average transverse energy with depth can be written

$$
\begin{align*}
\frac{\partial \bar{E}_{\perp}}{\partial z} & =\int d E_{\perp} E_{\perp} \frac{\partial g}{\partial z} \\
& =\int d E_{\perp} E_{\perp}\left(D^{\prime} \frac{\partial g}{\partial E_{\perp}}+D \frac{\partial^{2} g}{\partial E_{\perp}^{2}}\right)
\end{align*}
$$

Using integration by parts and the fact that $g$ is essentially a delta function $g\left(E_{\perp}, z\right)=\delta\left(E_{\perp}-E_{\perp}^{\circ}\right)$ at depth $z_{0}$, we get

$$
D\left(E_{\perp}^{0}\right)=\int_{0}^{E_{1}^{0}} d E_{\perp} \frac{d \bar{E}_{1}}{d z}
$$

Where $d \bar{E}_{\downarrow} / d z$ is for a group of monoenergetic ions of transverse energy $E_{\perp}$ averaged over the accessible area. Thus the diffusion function can be determined directly from the rate of change in average transverse energy as a function of depth.

Therefore, since the diffusion function can be determined in terms of well modeled physical properties, as will be seen in the next section, it is thus possible to determine the transverse energy distribution as a function of depth. One method of solving equation 2.1.6 for $g$ is through a numerical technique such as a finite difference method. The rest of this chapter is concerned with various approaches used to determine the rate of change in the average transverse energy with depth.

If one assumes that nuclear ( $n$ ) and electronic (e) contributions are independent functions of energy then the rate of change of average transverse energy with depth can be written as a linear combination of each term, this is written as

$$
\frac{\mathrm{d} \overline{\mathrm{E}}_{\perp}}{\mathrm{dz}}\left(\mathrm{E}_{\perp}\right)=\frac{\mathrm{dE}}{\mathrm{a}} \mathrm{dz}\left(E_{\perp}\right)+\frac{\mathrm{dE}}{\mathrm{~L}}, \mathrm{a}\left(\mathrm{E}_{\perp}\right)
$$

Where subscripts $a, n$ and $e$ stand for aligned, nuclear and electronic respectively.

Equations in the remainder of the thesis will be expressed in either transverse energy, $E_{\perp}$, or in reduced transverse energy, $\varepsilon_{\perp}=2 E_{\perp} / \Psi_{1}^{2} E$, formats.

### 2.2 Increase in Average Transverse Energy: Nuclear Component

Lindhard's ${ }^{7}$ treatment (which should be consulted by the serious reader) of the nuclear scattering contribution to the increase in average transverse energy of the channeled fraction consists of summing momentum transfers to beam ions due to collisions with thermally displaced lattice atoms. Displaced atoms create a perturbation in the continuum string potential resulting in a force fluctuation, $d \vec{F}$, experienced by passing ions,figure 2.3.

figure 2.3: Geometry of displaced lattice atom relative to the string and the passing ion, from Shiott 1973.

When averaged over accessible area and thermal displacement of lattice atoms the fluctuations become proportional to the change in average transverse energy, written as

$$
\left(\mathrm{d} \bar{\Sigma}_{\perp} / \mathrm{dz}\right)_{n, a}=\mathrm{d}^{3} \psi_{1}^{3}\left\langle\mathrm{~d} \overrightarrow{\mathrm{~F}}^{2}\right\rangle /\left(2 \mathrm{Z} 1 \mathrm{Z} 2 \mathrm{e}^{2}\right)^{2} \quad 2.2 .1
$$

The two dimensional thermal vibration amplitude distribution is assumed to be gaussian with an RMS value of $\rho$.

Equation 2.2.1 is a function of $\varepsilon_{\perp}$ as a consequence of averaging over the accessible area, $A\left(\varepsilon_{\perp}\right)$. When averaging over the accessible area a uniform distribution resulting from statistical equilibrium is as sumed.

The result is expressed in terms of a nuclear reduction function
$\gamma_{n, L}$, which is given by the ratio of the increase in average transverse energy for the channeled and random beams, given as

$$
\left(\mathrm{d} \bar{\varepsilon}_{\perp} / \mathrm{d} z\right)_{n, a}=\left(\mathrm{d} \bar{\varepsilon}_{\perp} / \mathrm{dz}\right)_{n, r} \cdot \gamma_{n, L}\left(\varepsilon_{\perp}\right) \quad 2.2 .2
$$

The increase in average transverse energy for the random beam is proportional to the theoretical random nuclear (nr) stopping power, written as

$$
\left(\mathrm{d} \bar{\varepsilon}_{\perp} / \mathrm{dz}\right)_{n, r}=-(\mathrm{M} 1 / \mathrm{M} 2)(\mathrm{d} \varepsilon / \mathrm{dz}) \quad 2.2 .3
$$

Where the subscript $r$ stands for the random system and M1 and M2 are the masses of the projectile and target atom respectively.
$\gamma_{n, L}\left(\varepsilon_{\perp}\right)$ evaluated to first order in $s / r$, the ratio of displacements of lattice atom and projectile relative to lattice position, yields

$$
\gamma_{n, L}\left(\varepsilon_{\perp}\right)=\frac{1}{\operatorname{Ln}} \frac{\rho^{2}}{(\mathrm{Ca})^{2}} \frac{1}{2}\left(1-e^{-\varepsilon_{\perp}}\right)^{3}\left(\frac{2}{3}+e^{\varepsilon_{\perp}}\right) \quad 2.2 .4
$$

Where Ln is logarithmic and is derived from nuclear stopping power energy loss considerations.

In this formulation, for energies approaching the critical transverse energy, ie. $s / r \rightarrow 1$, the expansion becomes questionable; $\gamma_{n, L}\left(\varepsilon_{\perp}\right)$ is an order of magnitude smaller than the true value, in the most important region, where nuclear scattering dominates.

The paper by Shiott et al addresses the above deficiency. They examined the next highest contributing order in $s / r$ in the expansion of the force fluctuation from the continuum string and exact results for two other central forces. From this, they decided to modify the first order reduction function by requiring it to asymptote to unity at approximately the critical transverse energy. This was accomplished by including and adjusting the fitting parameter $f$ in the following $\stackrel{\text { equation }}{\gamma_{n, s}}\left(\varepsilon_{\perp}\right)=\frac{1}{\operatorname{Ln}} \frac{\rho^{2}}{(C a)^{2}} \frac{1}{2}\left(1-e^{-\varepsilon_{1}}\right)^{3}\left(\frac{2}{3}+e^{f \varepsilon_{\perp}}\right) \quad 2.2 .5$

In contrast to Schiott, Matsunami and Howe" in the latest paper treat nuclear scattering at transverse energies approaching the critical value in terms of a quantum theoretical description given by Kitagawa and ohtsuki. The reduction function can consequently be written as

$$
\begin{aligned}
\gamma_{n, L}\left(\varepsilon_{\perp}\right)+\gamma_{n, k}\left(\varepsilon_{\perp}\right) & =\frac{1}{2 \operatorname{LnCn}} \frac{\rho^{2}}{3 a^{2}}\left(1-e^{-\varepsilon_{\perp}}\right)^{3}\left(\frac{2}{3}+e^{\varepsilon_{\perp}}\right) \quad 2.2 .7 \\
& +\exp \left(-\frac{3 a^{2}}{\rho^{2}} \frac{1}{\left(1+\varepsilon_{\perp}^{*}\right) e^{i_{L}}-1}\right)
\end{aligned}
$$

Where Cn is a correction factor such that contributions from large angle scatterings are excluded. The restriction is made since the model is one where the diffusion process is being exploited. This is accomplished by limiting scattering trajectories to those in the channeled fraction that remain channeled. The term $\varepsilon_{\perp}^{*}$ is equal to $3 \mathrm{a}^{2} / \mathrm{r}_{0}^{2} ; \gamma_{n, k}\left(\varepsilon_{\perp}\right)$ is the reduction function of Kitagawa and Ohtsuki.
2.3 Increase in Average Transverse Energy:

Electronic Component

In Lindhard's treatment the electron scattering contribution to the increase in average transverse energy of the channeled beam is normalized to the random nuclear scattering component. In order that all formulations are in the same units the results will be normalized to the random electronic component.

For an amorphous solid, ie. a random distribution of nuclei, the electron distribution can be considered to be uniform with average electron density $\rho_{0}$ equal to $Z 2 \mathrm{~N}$. For this case, the change in average transverse energy for the random electronic component can be written as

$$
\frac{\mathrm{d} \bar{\varepsilon}_{ \pm}}{\mathrm{dz}}=\frac{\mathrm{m}}{2 \mathrm{M1}} \frac{\mathrm{~d}}{\mathrm{Z1} \mathrm{Z2} \mathrm{e}^{2}} \text { Se } \rho_{0}
$$

Where Se is the theoretical stopping cross section per electron for high velocity incident ions．Increase in average transverse energy can be attributed to the increase in average square fluctuation in angle from momentum transfers due to individual projectile－electron collisions．The term $m$ is the electron mass．

For an aligned beam，the uniform distribution of electrons must be replaced by the cylindrically symmetric electron density $\rho(r)$ consistent with the standard continuum potential，ie．a single string model．From statistical equilibrium，projectiles will be distributed with equal probability over their accessible areas．Thus，evaluation of the aligned electronic term requires an averaging，〈．．．〉，over the accessible area and is written as

$$
\frac{\mathrm{d} \overline{\varepsilon_{土}}}{\mathrm{dz}}=\left\langle\frac{\mathrm{m}}{2 \mathrm{M}} \frac{\mathrm{~d}}{\mathrm{Z1} \mathrm{Z2} \mathrm{e}^{2}} \text { Se } \rho(\mathrm{r})\right\rangle \quad 2.3 .2
$$

The result of the above mentioned derivation can be formulated in terms of a reduction function，given by

$$
\left(d \overline{\boldsymbol{\varepsilon}}_{\perp} / d z\right)_{e, a}=\left(d \overline{\boldsymbol{\varepsilon}}_{\perp} / d z\right)_{e, r} \cdot \gamma\left(\varepsilon_{\perp}\right) \quad 2 \cdot 3.3
$$

The reduction function for the electronic term is thus the ratio of the aligned to random electronic increase in average transverse energy and is shown below

$$
\gamma_{e, L}\left(\varepsilon_{\perp}\right)=\left(1-e^{-\varepsilon_{\perp}}\right) \quad 2.3 .4
$$

For this derivation the stopping cross section per electron，Se，has been assumed to be independent of electron density and is proportional to the logarithm of the ratio of maximum energy transfer divided by average ionization energy per atom，Le $=\log \left(2 \mathrm{mv}^{2} / I_{0}\right)$ ，$I_{\text {o }}$ is approximately $\mathrm{Z} 2 * 10 \mathrm{eV}$ ．

Bonderup et $a 1^{8}$ instead of using the average ionization energy, as Lindhard did for Le, used a form originally derived by Lindhard from a dielectric approach, written as

$$
\operatorname{Le}=\log \left(2 \mathrm{mv}^{2} / \hbar \omega\right)-1 \quad 2.3 .5
$$

Now, when averaging over accessible area the additional term $\omega$, $=\left(4 \pi \rho e^{2} / m\right)^{1 / 2}$, the classical resonant frequency, must be taken into account because of the added dependence on electron density. The reduction function now evaluates to

$$
\gamma_{e, B}\left(\varepsilon_{\perp}\right)=\left(1-e^{-\varepsilon_{\perp}}\right)\left(1+\frac{\alpha}{L e} \ln \left(\frac{1}{1-e^{-\varepsilon_{\perp}}}\right)\right) 2.3 .6
$$

This formulation gives the same result for energies approaching the critical transverse energy but modifies the contribution from the channel centre for low transverse energy ions. $\alpha$ is a function weakly dependent on $\varepsilon_{\perp}$.

Shiott et al modified the previous paper's method by correcting for the fact that electrons outside a radius $r_{0}$ had been neglected in averaging over the accessible area. They kept the standard electron density out to $a$ radius $r_{c}$ and then set the electron density to $a$ constant $\rho_{0}$ outside of this radius so that the total number of electrons per target nucleus would equal the atomic number $Z 2 . r_{c}$ is approximately $r_{0} / \sqrt{2}$. The reduction function can then be written as

$$
\begin{array}{cc}
\text { same as 2.3.6. } & \left.r<r_{c} \text { or } \varepsilon_{\perp}\right\rangle U\left(r_{c}\right) \\
& 2.3 .7 \\
X_{e, s}\left(\varepsilon_{\perp}\right)=\frac{\rho_{0}}{N Z 2} \frac{(L e-1)}{L e} & r>r_{c} \text { or } \varepsilon_{\perp}<U\left(r_{c}\right)
\end{array}
$$

Matsunami and Howe's treatment, though similar to Shiott et al's, introduces a significant improvement into the continuum string model description of the electronic scattering contribution to increase in average transverse energy. This is accomplished by summing the standard electron density contributions from neighbouring strings in order to estimate the average electron density in the channel centre. Since the resulting electron density in the channel centre is approximately constant they divided the transverse real space into two regions. These regions are the channel centre, where a constant electron density is assumed, and string region, where the electron density is well described by the standard continuum potential electron density. The electron density in the channel centre is estimated using a multi-string formulation which partially takes into account the geometery of the channel. Recognizing that use of the standard charge density at these large distances may not necessarily be a good representation, in practice they use the constant electron density as a fitting parameter when fitting the theoretical dechanneling curves to experimental curves. The starting point is normally then the value determined for the standard electron density. Their formulation of the reduction function, once this is taken into consideration, can be written as

$$
\begin{array}{ll}
\gamma_{e, m}\left(\varepsilon_{\perp}\right)=\alpha^{\prime}\left(1-e^{u_{t}-\varepsilon_{\perp}}\right)\left(1-\frac{1}{\operatorname{CeLe}} \ln \left(1-\frac{e^{\varepsilon_{\perp}}}{1+\varepsilon_{\perp}^{0}}\right)\right. & r \leqslant r_{t}^{0} \\
\gamma_{e, m}\left(\varepsilon_{\perp}\right)=\gamma_{e}^{0}=\rho_{0}(L e-1) / N \text { Z2 Ce Le } & 2.3 .8
\end{array}
$$

Ut is the potential at which the transition from the channel centre to the string region occurs, Ce is a equal to (Le-1) / Le and $\alpha$ 'is given
approximately by $1-\gamma_{e}^{0}$. One important feature of Matsunami and Howe's treatment is that their formulation yields an analytic equation for the diffusion function which greatly facilitates the evaluation of the diffusion - like equation.
2.4 Comparison of Reduction Function Components

Figure 2.4 exhibits the relative sizes of the various reduction function components for protons on copper at 56 K , figure 2.4 .

figure 2.4: comparison of reduction function components

When comparing the relative influences of the terms the electronic reduction function must be divided by Le/(2 Ln Z 2$)$, which here evaluates to 195. This is due to the fact that the electronic
term must be renormalized to the random nuclear increase in average transverse energy. Thus the electronic term dominates the diffusion process for reduced transverse energies from zero up to approximately one; the nuclear term predominates for energies above one.

It is thus now easy to see why Bonderup et al's solution of Lindhard's reduction functions resulted in such a poor fit to experimental data. The electronic reduction function decreases unphysically to zero for zero transverse energy; this will result in a much too slow increase in transverse energy for well channeled ions. The nuclear reduction function does not reach the value that would be expected for ions in the random fraction; this results in a great decrease in diffusion for large transverse energy ions. These flaws can be seen to have been corrected for both reduction functions in the equations of Shiott et $\mathrm{al}^{9}$ and Matsunami and Howe and thus it can be appreciated why these formulations better describe experimental dechanneling fractions. Matsunami and Howe's nuclear reduction function, at low transverse energy, differs from Lindhard's due to the nuclear correction factor Cn. Also, Matsunami and Howe's electronic reduction function differs from Shiott et al's due to the term Ce. Shiott et al's and Matsunami and Howe's theoretical dechanneled fractions both agreed with experiment up to 1980. The agreement between theory and experiment is very good when Matsunami and Howe's treatment is combined with Moore's analysis of the experimental data.

## 3. Experimental Dechanneling: RBS Background

The experimental investigation of dechanneling in copper single crystals was carried out using Van de Graaff accelerators at Chalk River Nuclear Laboratories and Guelph University. The raw data was the yield of ions backscattered and measured as a function of energy using a solid state detector, figure 3.1. The solid state detector can be considered to be $100 \%$ efficient and it has an energy resolution of about 10 keV which translates to a depth resolution of 0.1 um for 1 MeV protons on copper. The solid angle subtended by the detector is approximately 0.01 steradians.

figure 3.1: random and single scattering theory yields, backscattering geometry, plural scattering

Converting an energy axis to a depth scale requires the knowledge of energy losses experienced by ions interacting with the lattice atoms. For ions that backscatter from a target atom, the ratio of kinetic energies after and before the collision yield the kinematic factor $k^{2}$, written as ${ }^{5}$

$$
k^{2}=\left\{\frac{\left(1-\left(m_{1} / m_{2}\right)^{2} \sin ^{2} \theta_{3}\right)^{1 / 2}+\left(m_{1} / m_{2}\right) \cos \theta_{3}}{1+m_{1} / m_{2}}\right\}^{2} \quad 3 . .1
$$

Thus, the energy of an ion that backscatters from the surface is given by $E=k^{2} E$. Those ions that backscatter at depth also lose energy due to inelastic multiple scattering along their ingoing and outgoing paths. Semi-empirical tabulations for the rate of energy 16,17 loss, $S(E)$, exist; from this data an energy-depth relationship can be calculated using the following equations
ingoing $\quad E_{1}=E_{0}-S\left(E_{0}\right) d z / \cos \theta_{1}$

$$
E_{i}=E_{i-1}-S\left(E_{i-1}\right) d z / \cos \theta_{1}
$$

outgoing

$$
E_{i-1}=k^{2} E_{i}-S\left(k^{2} E_{i}\right) d z / \cos \theta_{2}
$$

$$
E_{i}^{\prime}=\ldots\left(E_{i-z}=\left(E_{i-1}-S\left(E_{i-1}\right) d z / \cos \theta_{2}\right)\right) 3 . .2
$$

This assumes that the stopping power is constant over each slab (shown in figure 3.2); precision will increase for thinner choices of slab thickness.

figure 3.2: energy-depth slab diagram

Therefore it can be seen that the random yield can be associated with both an energy and depth scale as in figure 3.1. Using a single scattering theory ${ }^{13}$ and scattering cross section the theoretical yield for particles scattering through an angle $\theta_{3}$ can be calculated. In this
formulation the Rutherford scattering cross section has been corrected for deviations due to screening from orbital electrons. The cross section is written as

$$
\sigma(E)=F(E) \sigma_{R}(E)=\left(1-\frac{.049 \mathrm{Z1} \mathrm{Z2}}{} \mathrm{Z}^{4 / 3}\right)\left\{\frac{\mathrm{Z1} \mathrm{Z2} \mathrm{e}^{2}}{4 E \sin ^{2}\left(\theta_{3} / 2\right)}\right\}^{2} 3 . .3
$$

Figure 3.1 shows a comparison of the normalized single scattering and experimental yields. The inset graph, curve D, is the ratio of these curves and indicates the contribution to the experimental data due to multiple small angle/ plural large angle scattering. For 1 MeV protons on copper the effect rises to about $25 \%$ at 3.5 um . When the ion beam is well aligned with a major crystallographic direction an aligned spectrum results, figure 1.1. The suppressed yield, behind the surface peak, is a result of a decrease in nuclear scattering probability.

A comparison between the aligned and random spectra will allow a determination of the dechanneled fraction.

### 3.1 Conceptual Basis for Data Analysis

Ions with sufficiently large transverse energies, such that they are not bound by the coulomb barrier of the channel and therefore interact normally with the lattice, are said to be dechanneled and are thus part of the random fraction. These ions experience a stopping power equivalent to that experienced by ions traversing an amorphous solid. In contrast, the stopping power experienced by channeled ions is reduced compared with that experienced by ions in the random fraction. This is due to the fact that projectiles in the channel centre interact almost solely with channel electrons with the effect of the nuclei gradually increasing as the string is approached. In the
amorphous system a projectile interacts more or less in a constant manner with a random array of nuclei and their electron distributions. In the aligned single crystal case, due to the different stopping powers, it is easy to imagine a family of trajectories for which the emergent energy, after backscattering, will be constant. These paths form a continuum with end members illustrated by paths $a$ and $c$ in figure 3.3. In path a ions dechannel at the surface; in path $c$ ions dechannel and immediately backscatter at maximum depth for the emergent energy of interest.

figure 3.3: trajectories with constant emergent energy

It must also be kept in mind that single scattering is only true for ions backscattered at the surface and, in a sense, at the point of maximum depth. All other ions in the random fraction of the beam will undergo multiple small angle/ plural large angle scattering to a certain degree.

Thus, the fact that there is no unique trajectory associated with a particular emergent energy and, also, that the ions actually undergo multiple small angle/ plural large angle scatterings must be taken into account when extracting the dechanneled fraction in an analysis of the aligned and random spectra.
3.2 Extraction of the Dechanneled Fraction, $X(z)$

For an amorphous solid a simple proportionality can be written for the backscattered yield as a function of fluence, I, solid angle subtended by the detector, $\mathrm{d} \Omega$, target layer thickness, dz , and the atomic density $n$, this is given by

$$
Y \propto I n d \Omega d z
$$

The constant of proportionality is called the scattering cross section, $\sigma_{R}$. Rewriting equation 3.2 .1 in terms of yield per unit energy gives

$$
y=I n d \Omega d z \sigma_{R} / \mathrm{dE}_{1} \quad 3.2 .2
$$

Since $\sigma_{R}$ varies as $1 / E_{r}^{2}, 3.2 .2$ can be rewritten as

$$
y=K n I d z / E_{n}^{2}(z) d E_{1} \quad 3.2 .3
$$

Where K is a constant. Figure 3.4 illustrates the parameters.

figure 3.4: random yield $\begin{gathered}\text { parameters }\end{gathered}$
figure 3.5: aligned yield parmeters

For an aligned beam an added feature is that backscattering can not occur unless an ion has made a transition to the random fraction, figure 3.5, the rate of transition as a function of depth is $d X\left(z^{\prime}\right)$. Thus equation 3.2 .3 when written in terms of the random yield for the single scattering theory evaluated at the surface yields the following equation

$$
\mathrm{y}\left(\mathrm{E}_{a}\right)=\mathrm{y}_{r, 0} \mathrm{E}_{0}^{2}\left[\mathrm{~S}_{r, 0}\right] \sum_{i} \mathrm{dz} \quad \mathrm{~d} X\left(z_{i}^{\prime}\right) / \mathrm{E}_{d}^{2} \mathrm{dE} E_{a}\left(z_{i}^{\prime}\right) \quad 3.2 .4
$$

Where $\left[S_{n, 0}\right]$ the surface channel stopping power factor, is given by

$$
\left[S_{r, 0}\right]=k^{2} S_{r}\left(E_{0}\right) / \cos \theta_{1}+S_{r}\left(k^{2} E_{0}\right) / \cos \theta_{2} \quad 3.2 .5
$$

The sum is over all pairs of depths $z \& z^{\prime}, z^{\prime}<z$, such that the emergent energy is $\mathrm{E}_{\mathrm{a}}$.

Two cases should be considered in order to take into account the multiple small angle/ plural large angle scattering correction, D :
i... for an ion that backscatters immediately after dechanneling at maximum depth there can be only one large angle scattering event ( a D factor of one).
ii... for an ion that dechannels at the surface the $D$ factor is the ratio of the random to single scattering theory yields, inset graph in figure 3.1 .

As it has not been attempted, to date, to model the multiple/ plural scattering for path combinations between these extremes, a linear approximation of the variation between these end members has been assumed.

The aligned yield can now be expressed in terms of the single scattering theory formulation taking into account the multiple/ plural scattering factor, $D_{z_{i}}^{\prime}\left(E_{a}\right)$, at a particular energy as shown below

$$
y\left(E_{a}\right)=y_{r_{i},} E_{0}^{2}\left[S_{r, 0}\right] \sum_{i} d z d X\left(z_{i}^{\prime}\right) D_{z_{i}}\left(E_{a}\right) / E_{d}^{2} d E_{a}\left(z_{i}^{\prime}\right) \quad 3.2 .6
$$

Variation in $E_{d}^{2} \mathrm{dE}_{\boldsymbol{a}}$ for rechanneled ions has been neglected since it would be computationally difficult to take into account.

Equation 3.2.6 is the formulation by which the experimental data have been reduced and it is the same as that originally derived by

Moore ${ }^{13}$. By inverting this equation successive dechanneled fraction contributions, $d X_{i}$, starting from the surface slab can be calculated. Summing the individual terms, as a function of depth, will yield the dechanneling fraction $X(z)$.

### 3.3 Main Computer Program Description

Yield versus backscattering energy data for both the random and aligned spectra are averaged over a suitable interval, say 5 channel widths, starting just behind the surface peak. This data is then entered into the main program where channel numbers are converted into energies using the energy width per channel and the proper zero channel offset. Along with this data is entered the initial beam energy, the beam's fluence, the beam/target/detector system geometry, total number of data points and the channeled/random stopping power ratio The spectra are normalized using the ratio of the fluences. The kinematic factor is evaluated. Also calculated is the surface channel stopping power factor, equation 3.2.5.

With respect to the family of calculated curves which would be generated in an evaluation of the denominator in equation 3.2 .6 it was decided that, since they are approximately linearly spaced functions of depth, an interpolation scheme would be used to generate the values. Thus two curves would be determined and the rest would be interpolated. These are (1) the envelope of the end points of the family of curves corresponding to backscattering immediately after dechanneling and (2) the curve corresponding to dechanneling at the surface, schematically shown in figure 3.6 .

figure 3.6: interpolation scheme for $E_{d}^{2} d E_{\alpha}$
Also, the multiple/ plural scattering contribution is evaluated assuming a linear interpolation between the two end members enumerated in the cases considered in section 3.2 . These are determined at energies corresponding to the discrete data points and incorporated into two matrices.

Starting just behind the surface peak, the contribution of each layer to the dechanneled fraction is determined. For the first layer there is only one contribution, written as

$$
d X_{1}=y\left(E_{a 1}\right) E_{d}^{2} d E_{a}\left(z_{1}^{1}\right) / y_{r, 0} E_{0}^{2}\left[S_{r, d}\right] D_{z_{1}^{r}}\left(E_{a 1}\right) d z \quad 3.3 .1
$$

In the next layer the contribution from the first layer is subtracted and then the rest is attributed to the change in dechanneled fraction of this layer, given by

$$
\mathrm{d} X_{z}=\left\{\frac{y\left(E_{a z}\right)}{y_{v, 0} E_{0}^{2}\left[S_{v, 0}\right]}-\frac{d z D_{z_{1}^{\prime}}\left(E_{a z}\right) d X_{1}}{E_{d}^{2} d E_{a}\left(z_{1}^{\prime}\right)}\right\} \frac{E_{d d E_{d}}^{2}\left(z_{z}^{\prime}\right)}{\left.D_{z_{2}^{\prime}}^{\left(E_{a z}\right.}\right) d z} \quad 3.3 .2
$$

This process is then continued for all the rest of the data.
Next, the changes in dechanneling fraction in each layer are summed to yield the dechanneling fraction as a function of depth. Graphs of the experimental dechanneling fractions are shown in chapter 5.

## 4. Crystal Quality: Introduction

Before extraction of dechanneling rates from aligned and random spectra, for this thesis, it is necessary to ensure that high-quality single crystals are being used. In this chapter preliminary results from Guelph University, taken to test the preparation techniques, will be used in evaluating the quality of the crystals.

### 4.1 Crystal Preparation

An attempt was made to evaluate the significance of defects in the bulk by comparing X-ray patterns before and after annealing. One crystal was vacuum annealed just below the melting point for 72 hours and then the temperature was decreased by $10^{\circ} \mathrm{C}$ per hour back to room temperature. This procedure should reduce the overall number of mobile defects.

Surface preparation just prior to channeling was needed in order to remove oxides from the exposed surface and any defects in the near surface region due to implantation of protons and helium ions during previous runs. Crystals were cleaned by mechanical-polishing with a . 05 um alumina slurry on cloth for several minutes followed by a few minutes electro-polishing in a solution of $55 \%$ phosphoric acid and $45 \%$ distilled water at 1.6 V potential. These techniques removed roughly 0.03 and 3 um of copper per minute respectively. Polishing was performed in air and it is expected that a slight reoxidation will occur before the crystals can be introduced into the vacuum.

### 4.2 Crystal Quality Data

Laue X-ray diffaction patterns were examined prior to and after annealing. There were no discernible differences between Laue patterns for the same crystal slice before and after annealing and when compared to slices from the same crystal and another crystal. A couple of Laue spots appeared to have some internal structure which may be indicative of a little strain.

A small digression is necessary here before proceeding to the rest of the data.

Backscatter spectra yield useful information for determining crystal quality when the ion beam is brought into close coincidence with a major crystallographic direction. Three parameters which will be investigated are the axial half angle, $\Psi_{1 / 2}$, minimum yield, $X_{\min }$, and surface peak yield.

Their definitions and diagramatic representations follow:

$\Psi_{1 / 2}: \quad$| the angle at full width half minimum |
| :--- |
| of the channel dip, figure 4.1. |

| $X_{\text {min }}:$ratio of the minimum in the aligned yield <br> divided by the random yield, figure 4.1 and 4.2. |

| :--- |
| in the surface region, figure $4.2, ~ s h a d e d ~ a r e a . ~$ |

tilt scan
figure 4.1: angular dip spectrum

figure 4.2: aligned/random spectra

These parameters are functions of crystal structure and temperature and are sensitive to perfection of the lattice. They have been investigated experimentally and through computer simulations.

The following analysis is based on equations originally derived by Barrett ${ }^{18}$, using a computer simulation, as recorded in the Ion Beam 19 Handbook.

Axial half angles can be estimated through the following equation

$$
\psi_{1 / 2}=0.8 \mathrm{~F}_{R S}(\xi) \psi_{1, B}
$$

Barrett's characteristic angle, $\psi_{1, B}$, is given by 0.307 ( $\left.\mathrm{Zl} \mathrm{Z2} \mathrm{e}^{2} / \mathrm{E} \mathrm{d}\right)^{1 / 2}$; (Z1 $Z 2 \mathrm{e}^{2} / \mathrm{d}$ ) is a measure of the strength of the string's potential energy barrier; it's strength increases with a decrease in atomic spacing along the axial direction. $\xi$ is equal to $1.2 u_{1} / a$, the Thomas- Fermi screening radius, a, equals . $8855 \mathrm{a}_{0}\left(Z 1^{1 / 2}+Z 2^{1 / 2}\right)^{-2 / 3}$ and $\mathrm{a}_{0}$ is the Bohr radius. The constants . 8 and 1.2 are fitting parameters from Barrett's simulation, $d=d(\AA)$ is the axial atomic spacing and $E=$ $E(\mathrm{MeV})$ is the energy of the incident ion beam. $\mathrm{F}_{\mathrm{as}}$ is proportional to the square root of the continuum potential and is tabulated in other sources. There is an uncertainty in the half angle of $5-10 \%$ associated with the plane in which the tilt scan is performed. The one dimensional rms thermal vibration amplitude is shown below
$u_{1}=12.1\left\{\left(\frac{\phi(x)}{x}+\frac{1}{4}\right) \frac{1}{M 2 \theta_{D}}\right\} \AA \quad 4.2 .2$
Where $\phi(x)$ is the Debye function $\frac{1}{x} \int_{0}^{x} \frac{d t t}{e^{t}-1}$ and $x$ equals $\theta_{0} / T, \theta_{0}$ the Debye temperature and $T$ the sample temperature are in degrees Kelvin; M2 is in atomic mass units.

The minimum yield is given by the following equation

$$
X_{\text {min }}=18.8 \mathrm{~N} \mathrm{~d} \mathrm{u} 1_{1}^{2}\left(1+\zeta^{-2}\right)^{1 / 2} \quad 4.2 .3
$$

$N d u_{1}^{2} \pi$ represents the fractional area in the transverse plane occupied by thermally vibrating surface atoms. $\mathcal{J}$ is equal to $126 u_{1} / \psi_{1 / 2}$ d. $N$ is the atom density per unit cell. $X_{\text {min }}$ thus has a weak dependence on energy through $\mathcal{J}$ along with a stronger dependence on temperature through $u_{1}$. This equation represents what would be expected for a minimum yield determined just behind the surface peak for a depth of $1000 \AA$.

Surface peak yield can be estimated through
$L=\left(1+\varphi^{2}\right)^{1 / 2} \quad 4.2 .4$
$L$ is the number of atoms per string contributing to the suface peak yield. The factor 1 is the surface atoms' contribution, necessarily energy and temperature independent. The term $\rho^{2}$ is the contribution from partially shadowed atoms in the first few monolayers of the crystal. L increases with both increasing temperature (through $u_{1}$ ) and energy (inversely through $\psi_{1 / 2}$ ).

The number of atomic monolayers contributing to the experimental surface peak yield can be determined through the following equation

$$
L^{\prime}=\frac{A}{H} \frac{d E}{[S]} \frac{1}{d_{<>}}
$$

The total number of displaced atoms being equal to L'- L. A is the area of the surface peak yield in counts. $H$ is the height of the random spectra at the surface, $d E$ is the energy width of a channel in the multi-channel analyser, [ S ], defined in equation 3.2.5, is the
stopping power factor and $d_{<>}$is the axial lattice constant. These are illustrated in figure 4.3.

figure 4.3: illustrations of parameters in equation 4.2.5

In the surface approximation with $\theta_{1}=\theta_{2}=0$ for the Guelph data equation 3.2 .5 can be written as
$[S]=\left(k^{2}+1\right) S\left(E_{0}\right)$ 4.2 .6

Where the kinematic factor, $k^{2}$, is given by equation 3. .1.
The following table is a result of an evaluation of experimental data gathered at Guelph using the equations just presented. These measurements were made at room temperature though there may have been some radiative heat loss due to the fact that the cryo-shield was in close proximity, and was being held at liquid nitrogen temperatures. The Debye temperature has been taken as 315 K and rms thermal vibration amplitudes are tabulated in Appendix $I$.

A further test of the preparation technique can be made from an examination of dechanneling data for several crystals，figure 4.4.

figure 4．4：Dechanneling fractions for several copper crystals for 1 MeV protons along the＜ll0＞

Curves 1 and 2 are from slices of the same crystal, curve 2 has been taken after annealing. Curve 3 and 4 were runs from each machine and are from a slice of a totally different crystal.
4.3 Discussion

Annealing and X-ray data indicate that the bulk of each crystal is well ordered and that if there are any defects they are probably immobile.

Agreement between observed minimum yields and axial half angles and results of the computer simulation for a perfect crystal is good and would tend to support the contention that the surface is well ordered. Since agreement between theory and experiment is good for the minimum yields it is therefore probable that the uncertainty in choosing $a$ Debye temperature is not as serious as the error analysis value of 20 $30 \%$ would tend to indicate; thus the theoretical accuracy is likely much better than that recorded.

Surface peak yields indicate that the lattice is well ordered out to the surface, though patches of disorder may exist. Lower experimental values are most likely due to radiative cooling; no monitor of the target temperature could be made and it was therefore assumed to be at room temperature.

Dechanneled fraction curves are the same within their experimental accuracy and they would tend to indicate again that the crystals are highly ordered. Since annealing had no visible effect it can also be concluded that no significant concentration of mobile defects exist in the crystals.

Mozaic spread was found to be less than $1 / 2$ of a degree when aligning the beam along the $\langle 110\rangle$ axis over the surface of the crystal. The beam angular divergence was less than . 06 of a degree.

Hence, in conclusion, the techniques used in handling and preparing crystals has not injured their integrity and thus the experimental data will be that of a well ordered crystal with undeformed channels extending to the surface.
5. Results and Discussion: Introduction

In this chapter descriptions, physical interpretations and theoretical predictions will be made for experimental data from Chalk River. Experimental and theoretical results, some of which are tabulated in appendix II, are presented in graphical form. The Debye temperature has been taken to be 315 K .

$$
5.1 \quad 1 \mathrm{MeV} \mathrm{H}+\text { on Copper }
$$

The following tilt scans were taken within an energy/depth window, just behind the surface peak, of width 13 channels from channel 186 to 198; this is equal to approximately 0.3 microns. The surface edge is at channel 202 and channel widths are approximately $4.7 \mathrm{keV} / \mathrm{channel}$.

Tilt scans in figure 5.1 show the dependence of nuclear back scattering yield on tilt angle and thermal vibration amplitude; as vibration amplitude increases with temperature the dip and axial half angle decrease. Increase in thermal vibration amplitude will result in spreading of the continuum string and thus; its ability to steer ions away from the string decreases (this can be attributed to changes in the string potential). Also, the fact that string atoms move closer to the channel centre results in an increase in the probability of lower transverse energy ions undergoing large angle nuclear scattering and therefore contributing to the backscattered yield. Thus the increase in backscattered yield at lower energies will result in a decrease in the axial half angle.

Tilt scans in figure 5.2 show the yields' dependence on channel geometry as a result of the different axial lattice parameters. Along the $\langle 100\rangle$ axis the axial parameter is larger than for the $\langle 110\rangle$ axis. This results in a decrease in the critical angle and, see equation 4.2.1, therefore a decrease in the axial half angle. This can be understood in the context that increasing the spacing between string atoms will decrease their ability to steer ions away at lower transverse energies and thus an increase in backscattered yield would be expected.

As a consequence of the statistical nature of the backscattered yield the data has a precision given by the square root of the yield divided by the yield. Thus the error in $\Psi_{1 / 2}$ is approximately $10 \%$. Experimental and theoretical axial half angles are tabulated in table 5.1

```
table 5.1: Axial Half Angles
```

|  |  | 35K | 120K | 200K | 280K |  |
| :---: | :---: | :---: | :---: | :---: | :---: | :---: |
| $\langle 100\rangle 1.0 \mathrm{MeV}$ |  |  |  |  |  |  |
|  | theoretical | 0.81 | 0.74 | 0.69 | 0.65 | (7\%) |
|  | experimental | 0.78 | 0.69 | 0.62 | 0.56 | (10\%) |
| $\langle 110\rangle 1.0 \mathrm{MeV}$ |  |  |  |  |  |  |
|  | theoretical | 0.96 | 0.88 | 0.82 | 0.80 | (7\%) |
|  | experimental | 0.98 | 0.88 | 0.76 | 0.70 | (10\%) |

From table 5.1 a comparison between experimental and theoretical axial half angles shows good agreement. This indicates that the quality of the crystal appears to be good within the first one thousand atomic layers. A preliminary beam alignment was always performed on the periphery of the crystal just prior to this final alignment.

Before aligned spectra were recorded it was necessary to take quick tilt and azimuthal scans through the axis in order to verify the beam/axis alignment. The angle choosen from each scan was the average
of the mid-points from either side of the tilt scan yield through the dip. Reproducibility was very good and the precision was about one hundredth of a degree.

In figure 5.3 a tilt scan down an axis with two windows set at different depths was recorded. Alignment of the tilt scan yields tends to indicate that the channel is undeformed. Increasing yield with depth at a specific tilt angle is partially a consequence of the increase in scattering cross section with decrease in energy and, also, the increase in average transverse energy of the channeled fraction.

Figures 5.4 and 5.5 represent the temperature and axial dependence of the RBS backscattered yields. From these spectra dechanneled fractions shall be extracted.

RBS yields have been plotted against channel number. Decreasing channel number is equivalent to increasing depth and decreasing energy though these relationships are nonlinear.

figure 5.4: temperature dependent RBS spectra

Figure 5.4 shows a typical group of RBS spectra for 1 MeV protons on copper along the 〈110〉 axis. A strong dependence of the aligned yield with increasing temperature is observable. This dependence is a result of the increase in thermal displacement of lattice atoms with increasing temperature and results in an increase in force fluctuation
experienced by channeled ions. This increases the probability of transition to higher transverse energies at shallower depths and thus to the dechanneled fraction. Larger fractions of ions in the dechanneled portion of the beam will result in an increase in backscatter yield.

figure 5.5: axial dependent RBS spectra

Another observable feature from RBS spectra is the axial dependence of aligned yield, figure 5.5. The controlling factors are the same as those discussed for the tilt scans.
$X_{\min }$ values in table 5.2 were extracted from RBS spectra by averaging yields over 5 channels just behind the surface peak for both the aligned and random spectra and then taking their ratio. Five channels corresponds to a depth of approximately 0.1 um.
table 5.2:

|  | experimental | 0.009 | 0.014 | 0.020 | 0.027 |

From table 5.2 a comparison between experimental and theoretical values, using a Debye temperature of 315 K , shows very good agreement (discussion of experimental error in chapter 4). This parameter will be discussed a little later on in the text of this section.

Figures 5.4 and 5.5 are representative spectra plotted from the data in appendix II. We proceed with a discussion based on Moore's ${ }^{13}$ method of analysis of experimental data and Matsunami and Howé's" theoretical treatment. Curves are distinguished by dots for experimental values and solid lines for. theoretical values.

figure 5.6: axial dependent dechanneled fractions, 280K

Large differences in dechanneled fractions for the two axes at the same temperature is easily observed in figure 5.6. A good theoretical description should yield a good fit at all.temperatures. Variation in the rate of change of dechanneling for shallow and large depths will be demanding upon the theoretical treatment.

figure 5.7: channel stopping power dependent dechanneled fractions, 〈100〉

Figure 5.7 shows the sensitivity of dechanneled fractions on channel stopping power choosen for the analysis of experimental data. It is customary to use a value equal to 0.5 times the random stopping power. This corresponds to the stopping power which would be expected for well channeled ions. For the channeled beam as a whole, the
average channel stopping power would be expected to be greater than this minimum value. One can get a feeling for the average stopping power from data generated from the theoretical model of Matsunami and Howe, appendixII. Figure 5.7 shows the effect of varying this parameter on the dechanneled fraction. The obvious result that particles will penetrate to greater depths for lower stopping powers is evident.

figure 5.8: electron density dependent theoretical dechanneled fractions

Figure 5.8 shows the sensitivity of the theoretical dechanneled fractions as a result of varying the constant electron density parameter for the channel centre. Nuclear scattering dominates dechanneling at shallow depths. The effect of varying electron density
is to wag the dechanneled fraction at greater depths; this results since it takes time for electronic collisions to raise the average transverse energy of well channeled ions to the point where nuclear scattering becomes significant.

Through adjustment of the constant electron density parameter in the channel centre the theoretical dechanneling curves which result in a best fit of the experimental data along the $\langle 110\rangle$ axis is $0.875 \AA^{-3}$ and for the $\langle 100\rangle$ axis it is $0.7325 \AA^{-3}$.

Figures 5.9 and 5.10 show experimental and theoretical dechanneled fraction curves from an analysis of the experimental data using a channel stopping power of 0.5 times the random value and the best fit electron densities. Comments on these graphs will be made after figure 5.10 .

figure 5.9: temperature dependent dechanneled fractions, 〈110〉

figure 5.10: temperature dependent dechanneled fractions, 〈100〉

Before description of the figures a table of values showing the range of variation of dechanneling fractions with temperature and depth will be shown.
table 5.3: Range of variation in $d X / d z$ with $z, T$ from figures 5.9 and 5.10

Figures 5.9 and 5.10 result from an analysis of the spectra of 1 MeV protons on copper for the $\langle 100\rangle$ and $\langle 110\rangle$ axes. It is apparent that theoretical and experimental curves match extremely well. Deviations only occur at large depths and these increase slightly with increasing temperature. The tailing off of the theoretical values to values lower than the experimental values appears to be occurring above 20 to 30\% dechanneling.

In table 5.3 slopes change by up to factors of 4,3 and 2 as functions of temperature, depth and axis respectively. The theoretical treatment yields results comparable to the experimental results over a wide range of values. The ability of the theoretical description to match the large changes in dechanneled fractions and their rates of change for quite different geometries as functions of both depth and temperature is a testament to the treatment of the physical processes.

Defect dechanneling appears to be insignificant for several reasons. First, surface parameters indicate well ordered crystals with undeformed channels, at least in the surface region. Second, yields for two different crystals, having different histories, match very well and is thus self corroborating. Lastly, variation of dechanneled fractions with $z$ and $T$ in accordance with theory lends to the argument that crystal quality is good. Thus dechanneling due to residual defects appears to be insignificant. Also, since the crystals appear to be of high quality then $X_{\min }$ values are probably also good.

Therefore the poor precision in the theoretical $X_{\min }$ values is probably exaggerated.

One aspect investigated was the possibility that defects might have been induced during the course of the experiment.

While exposing crystals to the ion beam spectra were recorded with increasing temperature in order that the majority of well channeled ions would reach their maximum depth and would thus have a less detrimental effect upon later dechanneled fractions. Also, it is expected that damage introduced through implanting of protons will probably be annealed out at the temperatures of the investigation. When the temperature was cycled back to the starting temperature after a day of channeling no evidence of induced damage could be identified from the RBS spectra.

$$
5.2 \quad 2 \mathrm{MeV} \mathrm{H}+
$$

For the 2 MeV spectra the surface edge is at channel 202, alignment of the crystal was performed with a window 28 channels wide from channel 167 to 194 and which is equal to approximately 2.0 microns. The channel width was approximately $9.4 \mathrm{keV} /$ channel. $X_{\text {min }}$ were calculated using data averaged over 3 channels (equivalent to about 0.2 microns) just behind the surface peak.
table 5.4:
$\langle 100\rangle 2.0 \mathrm{MeV}$
56K

$$
\text { theoretical } 0.013
$$

$$
\text { experimental } 0.018
$$

$\langle 110\rangle 2.0 \mathrm{MeV}$

| theoretical | 0.009 | 0.018 | 0.028 | $(20-30 \%)$ |
| :--- | :--- | :--- | :--- | :--- |
| experimental | 0.009 | 0.018 | 0.031 | $(12 \%)$ |

The data in table 5.4 indicates that even though the $\langle 110\rangle$ axis appears to be alright the $\langle 100\rangle$ axis is probably marginal at best. When viewed in the light of the probable increased precision of the theoretical data then the data presented here indicates that the crystal quality is poor and thus it can not be compared directly with Matsunami and Howe's theoretical dechanneling curves.

Using the same electron density for the channel centre determined for a best fit of the 1 MeV data above, theoretical dechanneling curves were generated for 2 MeV protons on copper for the $\langle 100\rangle$ and $\langle 110\rangle$ axes. Plots of these against experimental data are shown in figure 5.11 and 5.12.

figure 5.11: temperature dependent dechanneled fractions, 〈110〉

figure 5.12: temperature dependent dechanneled fractions, 〈100〉

The fit for these sets of data are relatively poor, $25 \%$ at shallow depths decreasing to $10 \%$ at larger depths. The low temperature fits are fair and the fits get worse with increasing temperature.

One mistake, in hindsight, may be that angular scans were not taken over a small enough energy range. Thus the half angles could not be used as a measure of the quality of the crystal.

The fits along with the minimum yields appear to indicate that the crystal is flawed in some way, most probably in the first two microns as attested by the quick divergence of the experimental and theoretical values for the $\langle 100\rangle$ axis, either through the prevacuum preparation technique or some inherent or induced flaw such as a high defect concentration.

Unfortunately a second run on a different crystal was not performed
as a check on the validity of the first run．Lack of data on the other suface parameters hampers any attemp to make a definative statement about crystal quality other than that it is dubious．

## 5．3 A Look at Electron Densities

Equipotential plots in reduced energy for the $\langle 100\rangle$ and $\langle 110\rangle$ axes are shown in figure 5.13 along with cross sections through electron density distributions shown in figure 5．14；radii are indicated by letters in figure 5．13．These were produced using the standard potential；if a Moliere potential were used then electron densities at the channel centres would be about twice the values shown and thus correspond more closely with constant electron densities from the fitting procedure．

figure 5．13：

figure 5.14:
Electron density cross sections
for the $\langle 100\rangle$ and $\langle 110\rangle$ axes

Another measure of the validity of the constant electron densities used can be seen when the outer 11 electrons in the 3d and 4 s shells are averaged over the atomic volume. Cooresponding to this calculation the electron density is slightly more than 0.9 electrons per cubic angstrom.

Continuity is observed between channel centre and string regions for both equipotential and electron density plots for the <100〉 axis; the agreement with the $\langle 110\rangle$ axis is less readily justified due to the large discontinuity of the electron density with the long axis. The dotted potential lines in figure 5.13 were calculated assuming the constant electron densities from the fitting procedure. Thus, at least for the more symmetric axis, using the electron density as a fitting
parameter seems justified.

### 5.4 Summary

In summary, theoretical and experimental dechanneling fraction curves match excellantly for 1 MeV protons on copper when using constant channel centre electron densities of $0.875 \AA^{-3}$ and $0.7325 \AA^{-3}$ for the $\langle 110\rangle$ and $\langle 100\rangle$ axes respectively. Electron densities and their respective interatomic potentials were compared to those expected from a Moliere approximation and the 0.9 electrons per cubic angstrom electron density expected when the outer 3 d and 4 s electrons are averaged over their atomic volume. The relatively good agreement indicates that the electron densities obtained from the fitting procedure are reasonable. Subsequently one may conclude that for good quality single crystals both the experimental and theoretical analyses are well founded and thus the continuum string approach which yields excellant results with respect to channeling phenomena has shown itself to be very useful in modeling dechanneling phenomena.

Surface parameters have been shown to be useful in determining the quality of single crystals, namely in the case of the 2 MeV data. The conclusion which may be drawn from the minimum yields along with the poor match with the theoretical predictions is that the crystal was either damaged or that defects were encountered while polishing the crystal. This experience also highlights the necessity of taking spectra with several good crystals in order to have some confidence in the results.
